A tourniquet should be used in most cases to conserve time and facilitate neat workmanship. The exceptions are those cases in which the patient has an advanced arterial disease and a tight tourniquet might do further damage to the already seriously diseased vessels. Operating without a tourniquet in such cases enables the surgeon to judge whether the blood supply to the part is sufficient for good healing. When amputating at or near the shoulder or hip preliminary ligation of the large artery should be performed. Other vessels may be clamped as the incision proceeds, making application of a tourniquet unnecessary.

Secondary hemorrhage is usually caused by infection and may occur several days following the primary operation. When an infected stump is being treated the nurses and assistants should be cautioned with regard to the possibility of hemorrhage and a tourniquet should be kept in readiness for immediate application as an emergency measure. It should be remembered that tourniquets applied for a longer period than an hour may permanently damage the tissues.

Bone—Length of bone is a prime consideration in making properly functioning stumps. Bone should not be needlessly sacrificed merely to make a neat operation when bone length is needed for leverage and strength in the wearing of an artificial limb. The cut end of bone should not come in contact with the overlying skin flap if that can be avoided. An otherwise excellent stump may be ruined by necrosis of the skin flap which has not been sufficiently protected from bone pressure by interposing fascia or muscle tissue.

The treatment of the periosteum is important. Most surgeons now agree that the aponeurotic method (Hirsch Bunge) is the most satisfactory. The periosteum is completely removed for a distance of about 0.5 cm ($\frac{1}{4}$ inch) above the saw line. Before the bone is severed this should be accomplished by circling the bone with a knife and scraping the periosteum downward with a

sharp curet. By this procedure the saw does not pass through and shred the periosteum. In the presence of infection it is considered unwise to remove any periosteum above the saw line because of damage to the blood supply which predisposes to bone necrosis. The marrow is not disturbed. Its removal does not make healing any smoother and the blood supply in the medulla may aid in healing. As healing advances the open medullary cavity at the end is sealed with new bone.

The various musculoperiosteal and periosteal methods of treating the severed ends of bones are of doubtful value. The periosteum is very sensitive tissue and when it covers the bone end a tender stump or spur formation will result.

Bleeding from the cut end of the bone can usually be controlled by crushing the vessel against the bone with a blunt instrument or by applying hot moist compresses. Bits of fresh muscle tissue or bone may.

All rough portions of bone should be removed with saw, rasp and rongeur. Sharp or rough edges may by slight pressure cause necrosis of the overlying fascia or skin.

Sutures and Ligatures—Small vessels may be ligated with fine plain or chromic catgut. No. 0 chromic catgut is suitable for the ligation of large arteries and for sutures in the fascia. Non absorbable sutures of silk or silk worm gut are used in the skin. Interrupted on end mattress sutures make a smooth closure and prevent turning in of the skin edges. The skin stitches may be removed from clean wounds on the seventh postoperative day.

Use of Sulfonamides—Implantation of one of the sulfonamides is indicated in amputation wounds following trauma when infection exists in the extremity. Oral or parenteral administration of a sulfonamide may also be of value to prevent the spread of an infection from an infected amputation wound.

Drainage—With proper preparation of the skin, careful technique and thorough hemostasis it is doubtful if drainage is necessary in any clean amputation. A stump that is infected should always be drained with one or more small rubber tubes or rubber tissue drains. Drains placed between

stitches usually cause the least puckering of scar and delay in healing.

Dressings—For clean stumps a light gauze dressing applied snugly is sufficient. Care should be taken not to bandage the extremity above the stump so tightly that the circulation is impaired and edema increased. After twenty-four hours there is usually sufficient swelling to make the dressing uncomfortably tight and it should then be changed. Infected stumps require frequent changes of dressings.

Splinting especially at the knee is desirable in most cases to prevent contracture. A thin flexible splint such as a mica board well padded with cotton is efficient.

The Amputation Stump—Following operation the amputation stump should receive the same watchful care as any other postoperative wound. The first dressing should usually be made after twenty-four hours chiefly to promote the patient's comfort by relieving pressure due to edema. If a drain has been used it may be removed in forty-eight hours if no evidence of infection exists. Early signs of infection as evidenced by a rise in temperature, increased pain, edema, redness of skin, purulent discharge and leukocytosis are of great importance. At the first evidence of infection a sufficient number of stitches should be removed to give adequate drainage. Tension must be relieved to avoid sloughing. Warm moist boric acid compresses and drainage and increase the blood supply. It must be remembered that there may be some reaction with fever and swelling of a stump without infection. Absorption of blood and damaged tissue will cause a rise in temperature as will also a definite hematoma.

The average clean stump will heal in from ten to fourteen days and will be ready for fitting with a temporary artificial appliance in five or six weeks. During healing especially if prolonged by infection the stump should be placed in a position to prevent deformity. At the knee a flexed position is often most comfortable and the patient tends to maintain flexion until contractures develop unless prevented by splinting or frequent exercises and change of position. Flexion deformity at the hip commonly accompanies prolonged healing. This is avoided by insisting on proper position.

ful attention should be given to the removal of all dead bone and sinus tracts.

AMPUTATIONS OF THE UPPER EXTREMITY

and.—The indications for amputation of fingers or hands are usually trauma, in-

does not differ from amputation through the bone in any essential detail. It is not necessary to remove the articular cartilage.

All the fingers should be amputated at the metacarpophalangeal joints when damaged beyond any possibility of repair. Any part or all of the metacarpal portion of the hand

Fig 274—Skin incisions for finger and metacarpal amputations*

fection or deformity. The most careful judgment is necessary to avoid removal of too much of the hand. In many cases tissue that at first examination appears to be injured beyond repair later heals and functions normally. It should, therefore, be the rule that all parts possible be saved. Scarred, stiff, tender or deformed fingers which have lost their function should be amputated so as to be out of the way. The thumb deserves special consideration, since without this digit the function of grasping is largely lost. A single finger or even a portion of a single finger and a functioning thumb are superior to any artificial appliance.

Long palmar and short dorsal skin flaps are preferable (Fig 274). The palmar tissues are better adapted to pressure than the dorsal and will make firmer and less tender stumps. Flaps should be made of sufficient

may be removed. Long palmar and short dorsal flaps give the best results. Any part

Fig 275—Locations of choice for amputations of the upper extremity

exercise. At the shoulder the stump is maintained in abduction until the lessening of pain and tenderness permits exercise. Early fitting is recommended to restore function and avoid crippling habits. Elastic bandages are useful to reduce the edema in stumps and to promote shrinkage preliminary to limb fitting. Artificial limb fitters usually apply a leather shrinker for a few weeks preliminary to fitting. As soon as the wound is healed full range of motion of the nearest joint is important. To this end exercises are encouraged and massage is indicated. Massage also aids in reducing edema and tends to toughen the tissues. Frequent bathing with alcohol is also of value in toughening the skin.

Tender Stumps—The principal causes of tender stumps are infection, ulceration, disturbed circulation, neuromas, sensitive scars, nerve ends involved in scar tissue, bone spurs, periostitis, osteomyelitis, and neuritis.

Much difficulty may be experienced with furunculosis on the limb at the site of weight bearing. This is especially noticeable at pressure points below the knee and at the hip. When such infection exists it is wise to discontinue the wearing of an artificial limb until it subsides. The use of hot moist packs is recommended to allay the inflammation. Points of suppuration should be drained by small puncture wounds to minimize scarring as much as possible. Lack of proper hygiene of the stump is often responsible for such infection. Daily bathing followed by application of alcohol is useful in preventing skin infections. Eczema near the stump end, in folds of the skin and about scars is best treated by a plastic operation if proper hygiene fails. An acute infection about the end of the stump is easily detected and should receive the same type of treatment as infection elsewhere.

Persistent ulcers in the scar at the stump end are relatively common. The causes of chronic ulcerations are usually infection, direct trauma, and disturbed circulation. Just how much trophic disturbances are responsible for the development of ulcers on the stump is problematic. If the cause can be determined it should of course be removed. In some cases the removal of underlying bone infection, the proper adjustment of a limb or a plastic operation for a poorly

placed scar may give relief. In circulatory disease reamputation may be advisable. Perirrhatal sympathectomy is reserved for carefully selected cases in which there is some hope of success. During treatment the use of the artificial limb should of course be interdicted.

Stumps with redundant soft tissues are often edematous and sensitive. Ends of stumps may be blue and cold, especially leg stumps that are made too long. An ill fitting artificial limb may disturb the circulation and produce pain.

Neuromas which form on the cut ends of nerves are often sensitive if located where they receive pressure or irritation. They may be removed if necessary and the nerve above injected with 90 per cent alcohol. Occasionally a stump is found in which neuralgic pains are disturbing. This condition may also be corrected by shortening the nerves that are subject to irritation. The removal of focal infection in rare cases gives some relief.

Sensitive scars should be removed by a proper plastic operation and new scars placed in a position least exposed to trauma.

Periostitis and osteomyelitis should receive the treatment accorded elsewhere in the body. Sequestra should be located and removed as soon as separated from living bone. At times a change in the fitting of an artificial limb will relieve periosteal irritation.

Bone spurs are the result of a shredded periosteum or infection and should be removed if they produce symptoms. The mere presence of a bone spur is not an indication for its removal.

Contractures constitute a deformity which is likely to occur if the proper treatment is not carried out during the healing period. The best treatment is always prevention. The surgeon will be much aided by explaining to the patient how and why contractures follow amputations and urge his cooperation in maintaining the proper position of the stump and by starting early exercise of the nearest joint. After contractures have formed, massage with active and passive motion is of value. In the more severe cases traction with weights may be used. Operation may be resorted to in some cases but is often unsuccessful because the contrac-

ture frequently involves all the tissues in and about the joint including the joint capsule

Deformities due to contractures are of great importance from the standpoint of artificial limb fitting. It is obvious that any contracture at the hip, knee or ankle will render the part difficult to fit with a weight bearing prosthesis. The shorter the stump the greater the likelihood of contracture. Any contracture that has existed for a considerable period of time presents a serious problem and may necessitate reamputation. This is especially true of such deformities at the ankle or knee.

Scars—The proper placing of scars in locations to avoid friction is an important part of the operative technique. When a technique of choice is not practicable or when infection occurs, poorly located or adherent scars may be troublesome. When a scar is adherent to bone it may ulcerate or cause pain by direct pressure or as a result of traction due to motion of the stump in an artificial limb socket. Such a scar should be removed and an effort made to secure a covering of the bone ends with fascia and movable skin. If the bone is of sufficient length, reamputation may be performed. A scar that does not interfere with function should usually be left undisturbed. Bursae may form beneath scars over bony prominences rendering them more movable and less liable to irritation. Scars that are directly adherent to muscle tend to pucker and infold until chafing becomes disagreeable or painful. Such scars may be successfully excised and the fascia interposed between muscle and skin.

A *conical stump* results from a retraction of muscle which leaves the bone protruding beneath the skin or fixed to a scar. An amputee properly treated by guillotine amputation will frequently result in a conical stump. As a rule, such a stump is prone to be tender and to require reamputation.

Jerking stumps are an annoying complication of amputation and may be more or less persistent. The jerking usually occurs when the patient is thinking of his condition or when the stump is being examined. The basis of such a disability is usually nervous and difficult to control. In some cases the removal of tender nerve endings may effect a cure.

Any treatment should be accompanied by assuring the patient that the condition is curable and will be cured. Such patients can usually be fitted satisfactorily with artificial limbs.

Lengthening Stumps—An arm stump may be lengthened from $\frac{1}{2}$ to 1 inch by severing the insertion of the pectoralis major muscle near the humerus with temporary fixation of the stump in abduction. When the resistance of this muscular attachment is removed, the anterior axillary fold may be pushed upward. An operation has been suggested by Openshaw to lengthen a short forearm stump by removing much of the bulky muscle from the condyles of the humerus. Plastic operations on the hand to lengthen the thumb have been used with some success. By separating the first and second metacarpals an increased gripping power of the stub of a thumb may be obtained.

Skin Grafting—As a rule the skin grafting of ulcerated stumps is unsatisfactory if an artificial limb is to be worn. Free grafts and the accompanying scars do not tolerate weight or friction well and are apt to ulcerate. This does not apply to pedicle flaps of whole thickness skin or skin and fascia. Such flaps properly placed with due respect to the laws of plastic surgery may result in useful stumps.

Reamputation following the guillotine operation is indicated in a high percentage of cases. Other indications are protruding bone, infection, tender stumps as a result of bone spurs, redundant soft parts to reshape or shorten an unsuitable stump and the removal of troublesome scars.

If a plastic operation is to be done to reshape a stump or if an ulcer is to be removed and the stump shortened, the operation should be postponed until proper treatment has reduced the infection to a minimum and until a brawny edema has disappeared from the skin and subcutaneous tissues. An ulcer on a stump end is not a contraindication to reamputation or a plastic operation provided the surrounding infection is eradicated. It is wise to scar the surface of the ulcer with pure carbolic acid to avoid wound soiling before making a nearby incision.

Open or Guillotine Amputation—The

term guillotine as applied to amputations was revived during the first World War and the method was used extensively at the front. While not an ideal term it is probably in the literature to stay. As a general term it means any amputation in which the severed parts are left entirely open so as to aid drainage.

The open amputation in the strictest sense is always a method of second choice. In many instances it is undoubtedly life saving as well as being of great value in conserving the length of the bone. When possible it is made at a location which will later permit a higher final amputation to form a sound well functioning stump. Its chief objections are the necessity of another operation and the great prolongation of convalescence.

In the first World War this method was chiefly used to avoid or treat the much dreaded gas bacillus infection. It is now being used in the second World War in the zone of operations to prevent serious infections. It has a definite place in the treatment of the injured in civil life. When an extremity is traumatized this operation may be a life saving measure as it minimizes the operative treatment necessary during severe shock and conserves the length of the limb. Too often a closed amputation is performed for a mangled arm or leg at a high point where subsequent infection will ruin the stump when an open stump would have been the method of choice. The surgeon who undertakes traumatic surgery should be familiar with the modern sites of election for amputation from the standpoint of artificial limb wearing and should select the open method of amputation when it is indicated to make stumps of proper length. A patient with a foot crushed and lacerated beyond repair in a state of shock or with beginning gangrene from delayed treatment is a candidate for a guillotine amputation at or near the ankle to enable the surgeon later to do a clean operation through the site of choice in the middle third of the leg.

Acute pyogenic or gas forming infections are often an indication for the guillotine method of amputation. Infection of bones, joints and soft tissues when damaged beyond functional repair or when endangering life usually calls for the open operation. Am-

putation by the closed technique above an infected part is always a questionable procedure unless the infection has subsided and become local.

The technique of the open amputation depends somewhat on the location. It may be hurriedly done by direct circular section of all tissues by making skin and fascial flaps or by sectioning the tissues obliquely. The first method is rarely indicated. Skin and fascial flaps of moderate length should usually be made and the muscle cut from 5 to 7 cm (2 to 3 inches) longer than the bone to allow for retraction. The skin and fascial flaps may be packed open with gauze dressing or even temporarily sutured back to the skin above if severe infection is feared. When it is necessary to do the open amputation at a site most suitable for a final stump greater care should be used in operating with the hope that healing may take place with or without secondary closure and reamputation may be avoided. In such a case the nerves should be injected with 95 per cent alcohol and divided high; the muscle near the bone cut shorter than the superficial muscle and the skin and fascia carefully preserved together. It is unwise in the presence of infection or when infection is anticipated to remove periosteum above the line of bone section or to curet the marrow because of the danger of damaging the blood supply of the bone. Extension by adhesive straps with weight and pulley or with a Thomas splint may be used with success.

The postoperative treatment of the open amputation wound should receive close attention. Frequent inspection should be made to avoid pocketing of pus and ascending infection. The Carrel-Dakin method of treatment is satisfactory until the infection is localized and under control. Hot moist packs saturated with boric acid solution are of much value. Local application of one of the sulfonamide drugs is indicated in such fresh wounds to prevent the development of infection. In selected cases secondary closure may be considered if the wound is clean and the site of amputation is satisfactory. A sequestrum may form in an infected guillotine stump. Its presence is detected either by direct instrument examination or by x-ray plates. If the stump is to be closed by plastic operation without reamputation

careful attention should be given to the removal of all dead bone and sinus tracts.

AMPUTATIONS OF THE UPPER EXTREMITY

Hand.—The indications for amputation of fingers or hands are usually trauma, in-

does not differ from amputation through the bone in any essential detail. It is not necessary to remove the articular cartilage.

All the fingers should be amputated at the metacarpophalangeal joints when damaged beyond any possibility of repair. Any part or all of the metacarpal portion of the hand

Fig 274.—Skin incisions for finger and metacarpal amputations.*

fection or deformity. The most careful judgment is necessary to avoid removal of too much of the hand. In many cases tissue that at first examination appears to be injured beyond repair later heals and functions normally. It should, therefore, be the rule that all parts possible be saved. Scarred, stiff, tender or deformed fingers which have lost their function should be amputated so as to be out of the way. The thumb deserves special consideration, since without this digit the function of grasping is largely lost. A single finger or even a portion of a single finger and a functioning thumb are superior to any artificial appliance.

Long palmar and short dorsal skin flaps are preferable (Fig. 274). The palmar tissues are better adapted to pressure than the dorsal and will make firmer and less tender stumps. Flaps should be made of sufficient length to avoid tension when sutured. Length of bone should not always be sacrificed to obtain perfect skin flaps. Irregular flaps may at times produce good functional results.

The technic of disarticulation at an interphalangeal or metacarpophalangeal joint

may be removed. Long palmar and short dorsal flaps give the best results. Any part

E, Skin closed with interrupted sutures of silk or other non-absorbable suture material.*

ends of the bones with chronic catgut. Nerves should be divided high and all bleeding vessels ligated with plain catgut. Drainage is not necessary except when infection is present or anticipated.

Forearm.—An amputation through the wrist joint results in a poor stump as far as artificial limb fitting is concerned. Any ap-

pus infection of the hand and wrist develops, one should hesitate to amputate at the site of election in the forearm because of the danger of infection, the necessity of future amputation higher up and the producing of an inferior stump. From the standpoint of

* *See Operations of General Surgery*, W. B. Saunders Co., Publishers.

fitting an artificial prosthesis the site of choice for amputation through the forearm is at the junction of the lower and middle thirds (Fig 275) Good stumps are often produced by amputation just above the wrist but in many cases such a stump becomes sensitive because of a disturbance of the blood supply A forearm stump shorter than 2 inches cannot be successfully fitted with an artificial limb This measurement is taken from the biceps to the end of the stump with the arm flexed at a right angle As the biceps is inserted into the radius below the head it tends to push the artificial limb bucket off the stump when the elbow is flexed Disarticulation should not be performed through the elbow except as a temporary measure Such an amputation produces a bulbous stump which must be fitted with a laced socket above and a wide unsightly flange at the elbow

Arm and Shoulder—It has been mentioned in the previous section that it is usually unwise to disarticulate at the elbow joint. The most satisfactory arm amputation is made just above the condyles. An arm stump shorter than 3 inches measuring from the axillary fold is unsatisfactory for artificial limb fitting. Disarticulation at the shoulder is rarely indicated since it is wiser to leave the head of the humerus in its socket so as to prevent a flattening of the shoulder which is disfiguring and often may be detected through the patient's clothes. As in the forearm amputation anterior and posterior flaps of equal length are preferable. The pressure from an artificial limb is largely lateral therefore a scar placed on the end of the stump would be less likely to be irritated by a limb socket. Amputations through the surgical neck or at the shoulder require different types of flaps to avoid placing the scar near the point of the shoulder where it would be exposed to pressure.

Interscapulothoracic Amputation—Fortunately this amputation is rarely indicated. It is rather elaborate and usually associated with considerable shock. Certain tumors of the upper end of the humerus and scapula or extensive trauma to this region may make the amputation necessary. It is not advisable to perform such an amputation in the presence of acute infection.

AMPUTATIONS OF THE LOWER EXTREMITY

Foot and Ankle—Since the two chief functions of the lower extremities are locomotion and weight bearing it is important to consider amputations from the standpoint of future artificial limb wearing (Fig 277). Exceptional cases of course require special consideration—old age and other disabilities which prevent activity. Amputation of the toes does not as a rule cause great disability. Loss of a great toe is more likely to disturb the gait than the loss of any other toe. With the exception of the great toe it is wise not to leave a single toe on a foot when

Fig 27—Locations of choice for amputation of the lower extremity

the other toes are completely amputated. A single toe is likely to be painful and deformed and to cause greater disability than no toes. Amputation of the second toe is somewhat objectionable in that hallux valgus may be produced by lack of lateral support of the great toe.

Any amputation through the metatarsals will produce a good functioning stump provided there is sound healing and the scar is properly placed so as to prevent painful pressure points. The I frame operation which is a tarsometatarsal disarticulation will produce a useful stump provided the flexor and extensor tendons are properly fixed to the stump end so that they will retain their function. A loss of muscle bal-

ance is likely to result in contractures which will destroy the usefulness of the stump

Any amputation between the Lisfranc and the Syme is of doubtful value. The Chopart and Pirogoff (Fig 278) which have been the other classic amputations in this region have serious faults which often necessitate reamputation through the leg. The Chopart amputation is a mediotarsal disarticulation and frequently results in a poor stump because of muscle imbalance resulting in contracture of the muscles of the calf and the tilting downward of the stump end. The latter causes faulty weight

Fig 278—Skeletal lines of incision in several of the well known foot amputations (Redrawn from Orr)

bearing and difficult fitting. The Pirogoff is an osteoplastic amputation in which the posterior portion of the os calcis is retained in the heel pad and turned forward to unite with the tibia and fibula after removal of the malleoli. The first objection to this technique is the difficulty in obtaining sound healing between the posterior part of the os calcis and the lower end of the tibia. The second serious objection is the subsequent difficulty of fitting an artificial limb. Subastraloid disarticulations have much the same objectionable features as the Pirogoff. Practically the only argument in favor of

the Chopart, Pirogoff and other amputations through the tarsal bones is that they produce an end bearing stump which enables the patient to walk without an artificial limb. It is generally considered by surgeons of experience that the objectionable features of these amputations far outweigh the beneficial features. It is much better to discard all amputations between the Lisfranc and the Syme unless one of them is performed as a trial measure with the full understanding that reamputation may be necessary later.

The Syme amputation is made just above the malleoli, the heel pad being used to cover the bone ends. This amputation gives the patient an end bearing stump and enables him to go about his room without a crutch or artificial limb. There is division of opinion among surgeons in regard to the value of this amputation. Some give it high praise and others advise against it, stating that subsequent amputation through the leg is necessary in a high percentage of cases. Undoubtedly a properly made Syme stump has few objections and can be recommended. The fitting of a Syme stump with an artificial limb is difficult and results in an unsightly ankle in most cases.

Leg—From the standpoint of artificial limb fitting the best amputation above the ankle is through the middle third of the leg 7 inches (18 cm) below the knee (Fig 279). Amputation through the lower third of the leg is unsatisfactory because practically always the stump becomes atrophic, tender and cyanotic. Long leg stumps are also difficult to fit. A leg stump shorter than 2 inches (5 cm) below the biceps tendon with the knee flexed at right angles is unsatisfactory for fitting purposes. Removal of the entire fibula is indicated when a stump is shorter than 3 inches (8 cm). The old term site of election meant that an amputation should be performed about 4 inches below the knee so that a peg leg could be used with the knee for weight bearing in a kneeling position.

Thigh—It is well known that amputations through the thigh or at the hip are accompanied by more shock than those below the knee and this fact should be taken into consideration when judging a patient's operability. General or spinal anesthesia is used.

Disarticulation of the knee joint is rarely

advisable because of the resulting bulbous stump produced by the femoral condyles. Such stumps are difficult to fit with artificial limbs and are unsightly. They are inferior to those stumps produced by the Gritti Stokes or supracondylar amputations. The osteo-

vided and the tendon of the quadriceps extensor muscle sutured over the bone end as a long anterior flap. Callander has also described a tendoplastic amputation at the knee designed for weight bearing. Long anterior and posterior skin and fascia flaps are

Fig. 9.—Technique of leg amputation at the knee. A Anterior skin flap reflected. B Anterior skin flap reflected. F Skin flaps closed.*

plastic Gritti Stokes amputation at the knee when properly performed makes a good end bearing stump. The tendoplastic supracondylar amputation as described by Kirk with proper technique and after training may produce an end bearing stump not inferior to the Gritti Stokes. The femur is di-

vided and the hamstring tendons are severed at their insertions. The femur is divided just proximal to the adductor tubercle and the patella is removed from the rectus femoris tendon leaving a flange for the end of the

* Orr, *Operations of Cerebral Surgery*. W. B. Saunders Co., Philadelphia.

femur Callender states that his technic reduces mortality by lessening shock by shortening the period of bed rest by reducing the incidence of infection due to long flaps with little tension and few sutures by adequate drainage of serum from the wound and by decreasing the incidence of reamputation

An *interthoracoabdominal amputation* is a very formidable operation and is rarely indicated. In well selected cases it may be performed to remove extensive neoplasms of the ilium. The entire innominate bone or a portion of it may be removed with the lower extremity. The operative mortality rate is over 50 per cent.

Fig 280—Steps in the Grill-Stokes amputation technique. *A* Lines of the skin incisions. *B* Appearance after femur is sectioned and the articular portion of the patella is removed. Other thigh stumps should be made as long as possible in order to give strength and leverage for the wearing of an artificial limb. A stump shorter than $3\frac{1}{2}$ inches (9 cm) measured from the perineum has little more value for fitting purposes than a hip joint disarticulation.

KINEPLASTIC AMPUTATIONS

Any plastic operation on an amputation stump which enables it to transmit voluntary movement to an artificial limb or appliance is termed a kineplastic amputation.

* *On Operations of General Surgery* W. B. Saunders Co. Publishers

The points of attachment for prostheses on the amputation stumps are termed *motors* or *plastic motors*.

This highly specialized phase of amputation was first introduced to surgery by Giuliano Vanghetti an Italian surgeon, in the year 1896. While his work was experimental, it was a stimulus to others to make practical application of his suggestions.

Outstanding contributions to this subject have been made by Sauerbruch in Germany, G. Bosch Arana in South America and Putti, Pellegrini and others in Italy. Any one interested in the subject should read the works of these authors.

At present the practical value of kinematic amputations is somewhat difficult to estimate. Unless the surgeon is especially interested in this type of surgery, such methods should not be attempted. To make efficient kinematic stumps requires not only a knowledge of the necessary surgical technique, but an interest and knowledge in the manufacture and fitting of proper artificial appliances. This field of work has not been sufficiently developed for limb makers to interest themselves in fitting suitable prostheses. The results of present methods of fitting amputations of the lower extremity are so satisfactory that kinematic stumps offer little or no advantage. The greatest field for development will undoubtedly be in the arm. Any workable method which increases the ability to perform the finer movements of the fingers should be encouraged.

Plastic motors are commonly classified as club or clava, loop or ansa, muscle tunnel, tendon tunnel and pseudarthrosis. They are also frequently designated as unimotor, bi-motor and plurimotor, depending on the number of motors constructed. The club motor is a knob like mass of muscle or tendon covered with skin to which a loop or ring of a prosthesis may be attached. A loop motor is formed by joining opposing tendons and muscles and covering them with skin. The muscle tunnel motor is made by tunneling through the muscle tissue and lining the tunnel with a pedunculated flap of skin. The tendon tunnel is constructed in much the same manner as the muscle motor. The pseudarthrosis motor is constructed by

severing the bone near the stump end and leaving a bone segment in the distal muscle tissue, which is rendered mobile by the lack of union of the bone.

Any plastic motor to be efficient must have muscle power, a healthy skin covering a range of motion sufficient to move the artificial appliance, sufficient length and strength and a good solid surface for counterpressure. The range of motion of a motor should be at least 1 inch (2.5 cm) or, better, from 1½ to 2 inches (from 3 to 5 cm).

Fig 951—Lines of skin flaps and incisions for amputations through the lower extremity.*

It is possible to perform a primary kinematic operation. If it is to be done as a secondary operation, all possible tissue should be conserved at the primary amputation.

PROSTHESIS

Prosthesis (prothesis) is defined as the replacement of an absent part by an artificial one. While teeth and bony and soft part defects are included the term is most frequently applied to the fitting of artificial limbs.

An amputation stump should be ready for fitting with a prosthesis six weeks after a closed amputation or the repair of a gunshot stump unless healing has been delayed. When the suture line is healed physiotherapy is begun in order to mobilize the joints, strengthen muscles, reduce edema and toughen the skin. Daily massage and active passive and resistant exercises are prescribed. The skin is bathed liberally with alcohol and a tightly applied Ace bandage is continually worn. Free motion in all joints of a stump leg or arm and muscle power equal to that of the normal extremity are essential for the proper retention of a prosthesis. Ten days after operation the patient begins gently at first to pound the stump end with his open hand; next is practiced direct weight bearing on a soft pillow during the fourth postoperative week. This is essential in end bearing stumps and is valuable in making the non-weight bearing stump painless.

Early fitting with a temporary prosthesis produces a physiologic shrinkage of the stump and develops weight bearing points and the muscles necessary for propulsion. Pressure and use hasten the absorption of fat and edema and encourage the atrophy of muscle which has no further function. The end result is quite the opposite to what occurs if the stump is allowed to shrink by the atrophy of disuse aided by various types

of 'shrinkers'. Under the latter circumstances edema increases as a result of dependence; fat is deposited in the subcutaneous layers; joint deformities tend to occur; muscle power lessens and the stump becomes painful and useless. Changes in the soft parts of a stump of the lower extremity known as shrinkage continue for a period of approximately six months. The stump then assumes its more or less stationary form and is ready for a permanent prosthesis.

The fitting of a stump of the upper extremity with a temporary prosthesis is not as essential as in the lower extremity and many of the stumps may be fitted at once with a permanent type of prosthesis.

In the lower extremity there are two types of prosthesis: end bearing in which the weight of the body is borne on the stump end and bony point and cone bearing in which the weight is borne above the stump end and the stump itself acts as a lever actuating the prosthesis.

The Stume and Progoft stumps in the leg, the Griggs Stokes and the supracondylar tendoplasty stumps in the thigh are end bearing stumps and should be so fitted. All other stumps except certain other amputations through the lower third of the thigh are fitted by the second method. In the leg, the weight is borne by the shelving inner tuberosity of the tibia, the fibula below its head and by the cone bearing action of the soft parts of the stump itself against its rigid bucket. Weight must be relieved over the tender head of the fibula, the peroneal nerve below it and over the tubercle and the crest of the tibia. In the thigh the weight is borne on the tuberosity of the pelvis where the shelving upper edge of the thigh bucket is molded to receive it, supplemented by the thrust of the stump itself into the well fitting bucket.

The bucket or socket, that part of a prosthesis which is built to receive the stump should always be of rigid construction in the lower extremity. The best type of prosthesis for the lower extremity has knee, ankle and toe motion. The stump is covered and protected by at least one knitted white woolen stump sock. These socks are changed daily and kept meticulously clean to prevent skin infection. The prosthesis is secured in place by means of straps over the shoulders or is

attached by straps to a belt. The short or fat thigh stumps are further secured in position by the use of a pelvic band of metal and leather which is attached to the prosthesis with a jointed metal bar.

TYPES OF PROSTHESIS

Temporary Appliances—1 *Plaster of Paris*—This is constructed by the surgeon at the hospital or office and consists of a bucket which fits the individual stump. It is made of plaster of paris and supported on a peg crutch or metal set up. This type is all ways available and inexpensive and meets the necessary requirements.

2 *Molded Leather*—This type is factory made and consists of a molded semirigid leather bucket with leings which allows adjustments as shrinkage occurs. It is supported by metal side bars with joint motion in the knee, ankle and foot.

3 *Vulcanized Fiber*—This type is factory made, is obtainable in any quantity desired and is easily taken apart and rebuilt to fit the individual stump by any competent orthopedic mechanic. It is durable and cheap and simulates the permanent type in its mechanics. The thigh bucket and skin piece are made of fiber, the knee block and foot are of wood. Adjustments are easily made as stump shrinkage occurs. The below knee bucket is made locally of leather molded over a plaster mold of the stump which supplements the below knee fiber set up. This type of temporary prosthesis was adopted by the U. S. Army during the first World War.

Permanent Appliances—The permanent types of prosthesis are made of English willow wood covered with rawhide, vulcanized fiber and duraluminum. The rigid type of bucket is preferred. It is made of the following willow cut from a solid block to fit the stump, leather accurately molded and sewed to fit a model fiber shaped and molded by heat and pressure and duraluminum. Willow is lighter in weight than leather, it may split or crack, but it is ideal if properly fashioned. Leather is easier to mold but becomes

soiled with perspiration. The duraluminum leg may have a bucket of the same material but willow or leather is usually employed. In fitting certain stumps both willow and leather are used. Manufacturers differ regarding the construction and mechanical control of artificial feet, ankle and knee joints. The type which is made of the best material has the best design and is lightest in weight should be chosen.

The essentials of a satisfactory prosthesis are:

1 A properly fitted bucket.

2 An alignment of the prosthesis joints which must be at proper angles with the weight bearing line and must have proper lateral alignment.

3 Lightness in weight combined with durability.

The thigh prosthesis should be $\frac{1}{2}$ inch shorter than the normal leg to allow the amputee to swing through. The below knee prosthesis is made equal in length. It is important that the below knee bucket fit the stump snugly and extend beyond its length. Special types of prosthesis are required for the Progooff, Syme, Chopart and hip joint amputations. In the upper extremity the buckets are made of leather, fiber or willow. The so called utility arm with a split hook of the Dorrance type is probably the best working tool. There are several types of mechanical hands on the market; they are more expensive than the utility arm and dressier in appearance and are likewise a poor substitute for a normal hand. They are usually heavy and the weight is at the wrong end of the appliance.

XVI. INFECTIONS AND TUMORS OF BONE

ACUTE OSTEOMYELITIS

This term has come into general use and will probably continue to be the name generally accepted as designating an infection that may involve the entire bone—periosteum, cortex, medulla epiphyseal line shaft and epiphysis and including in its meaning similar pathologic lesions in all bones whether long, irregular or flat. In its narrow sense the word osteomyelitis was and sometimes is confined to infection of the medullary canal and the adjacent bone, and because the term is not very accurate many other titles have been suggested—periostitis, osteoperiostitis, periosteomyelitis, osteitis, epiphysitis etc., but in spite of objection and suggestion the term osteomyelitis is more and more used in its broad sense.

There are two exceptions to this nomenclature that are in more or less general use. If the infection is confined to the periosteum it is spoken of as periostitis, and where the infection is definitely within the bounds of cancellous bone most surgeons use the term osteitis. However, there is much confusion and looseness in the use of terms to designate infectious processes in the different elements that enter into the structure of bone.

History—Because many of the bones are near the body surface infections in them have been seen and discussed from the beginning of recorded surgical observations and many famous names are associated with the progress of understanding of the various phases of acute osteomyelitis. However in spite of the great mass of literature dealing with all phases of bone infection acute osteomyelitis still remains a disease that is often diagnosed too late to be treated promptly enough to prevent a high mortality rate, long illness, serious complications, permanent deformity and great economic loss.

Anatomy—The long flat and irregular bones have a somewhat different arrangement of the elements that enter into their structure. All of these elements—periosteum, endosteum, articular cartilage, compact and cancellous bone, epiphyseal line and cartilage, medullary canal and contents, haversian system and cortex together with the blood and lymph supply should be borne in mind. The differences in bone during body growth and in adult life must be considered. The relationship of bones to joints also enters into the anatomical problem.

The structure of the different bones is described in any good textbook of anatomy. There has been a great deal of controversy however as to the behavior of the periosteum and the arrangement of the blood supply. It is important to know just how bone renews itself when destroyed by disease, damaged by trauma or excised by the surgeon and there is considerable literature descriptive of the results of experiments on animals and observations on human bone during repair. Likewise there are a number of excellent studies of the blood supply of bone including that of Lexer and of Robert W. Johnson.

The periosteum has two surfaces, an outer fibrous one covering the bone and separating it from surrounding structures and an inner one loosely attached to the bone by many fine strands of connective tissue. This attachment is much less firm in children than in adults and especially so in children under two years of age. It is around this deeper layer that controversy has been waged as to what part it plays in the repair of bone. When torn away by trauma or lifted up by infection many osteogenic or bone-forming cells go with it and these cells play a major part in the formation of new bone. The periosteum covers the shaft of the long bones and is firmly attached to the cortex at the epiphyseal line but is not continuous with the articular cartilage. In young persons it dips down into the bone at the epiphyseal line. In the growing child the epiphyseal line is made of cartilage from the shaft side of which the bone grows in length. Because of this fact there is not very firm union between the shaft and epiphysis and separation due to trauma is common at this point. In young persons the blood supply is abundant along this line and comes from a number of directions—chiefly from the nutrient artery of the shaft and almost as abundantly from the side of the epiphysis where the blood enters the bone chiefly from a circular network of arteries just outside of and surrounding the articular cartilage. A third source of blood supply is from the periosteum but this supply is now known to be of less importance than was formerly supposed. When the blood vessels of young bones are injected a very beautiful and abundant network of end arteries is seen on either side of the epiphyseal line.

It was formerly supposed that the stripping up of the periosteum resulted in necrosis of the underlying bone because of interference with the blood supply but observation and experiment have established the fact that necrosis is caused by infection which kills the bone either by direct damage to the cells or by widespread embolism and thrombosis of the blood vessels.

The nutrient vessel in the long bones of the two extremities runs toward the elbow and away from the knee. This vessel divides soon after entering the bone and sends a main branch in either direction. The rich circle of blood vessels found in the expanded

ends around the articular cartilage are intimately associated with the epiphyseal line especially in those joints where the articular cartilage approaches close to the epiphyseal line and where the synovial membrane of the joint may overlay the junction between shaft and epiphysis.

Etiology.—Acute osteomyelitis is the successful invasion of bone by pyogenic micro-organisms, chiefly *Staphylococcus pyogenes aureus* (which is the organism at fault in about 75 per cent of the cases), the streptococcus *Staphylococcus albus*, the colon bacillus, the pneumococcus and very rarely the gonococcus. The typhoid bacillus is occasionally found but is associated with sub-acute and chronic osteomyelitis. These organisms are for the most part blood-borne, and the type of osteomyelitis which they produce is called hematogenous. There are several other avenues of infection however. Compound fractures or operations on bone followed by infection may cause osteomyelitis. Very rarely the bone may become infected by contiguity from a neighboring joint, or acute osteomyelitis may be secondary to infection in neighboring soft parts, osteomyelitis of the lower jaw is a very common complication of infected gums or tooth sockets and whitlow is complicated by infection of the terminal phalanx. Some infection of rib ends may follow thoracotomy, and perforating ulcers of the foot are apt to involve bone and periosteum. If the osteomyelitis is hematogenous and due to *Staphylococcus aureus*, the source of infection should be looked for in the skin—furunculosis, carbuncle, acne, infected fistulas etc. If, on the other hand the streptococcus is the causative organism, the original site should be sought in the mucous membranes of the mouth or nose, the tonsils or accessory sinuses. The pneumococcus is found in the blood stream in pneumonia occasionally bones or joints become the seat of a pyogenic infection and rarely the colon bacillus found in suppurations within the abdomen may enter, by way of the blood into osseous tissue.

Pathology.—Until recently the conception of the pathologic anatomy of this condition was cloudy and confused because the beliefs expressed long ago by surgeons and pathologists were accepted without being subjected to careful observation. Recently a number of investigators have helped to make clear

just what happens when bone is acutely infected. A number of things must be borne in mind. The youth of the patient largely influences the blood distribution the avenue of infection is important, the haversian canals and the bone between the periosteum and its loose attachment in the cortex the epiphyseal line and the break in periosteum at this point the medullary canal and its contents the endosteum the kind number and virulence of the infecting organism and the resistance of the host and predisposing factors such as trauma and exposure to cold all of these elements must be considered when one is confronted with a pathologic process that may begin with dramatic suddenness develop with amazing speed and end in tragedy almost before it is realized that anything serious is happening.

While the periosteum is usually involved in osteomyelitis as a part of the later spread of the infection throughout all the elements of the bone primary acute periostitis is in most instances a local process associated with trauma and confined to the periosteum and a thin layer of cortex. There is one type of primary severe acute periostitis however that is very destructive of the underlying bone and that is caused by trauma and local infection in the soft parts successfully invading the subperiosteal space and lead up to widespread separation of periosteum and infection of bone which may cause sequestration of the entire shaft. The writer has seen the entire metaphysis of the ulna lost in a case in which infection resulted from a break in the soft parts caused by treating a wart just below the elbow with strong nitric acid.

Localized infection of all the bony structures often follows compound fracture and is seen also as a complication of open reduction of fractures. This kind of infection however is not apt to be so virulent rapid or destructive as the hematogenous type when there is no fracture of bone or extension from a neighboring joint but an acute infection brought from some distant source in the body in the blood stream.

It is often impossible to say whether the disturbance in any given case begins as the result of the deposit and multiplication of organisms in the bone or whether the infection begins as one or more infarcts secondary to emboli and thrombosis. The very rapid and extensive involvement of bone in hectic thrombosis in the larger branches of the nutrient artery or in the blood vessels at or near the epiphyseal line.

In acute hematogenous osteomyelitis the process commonly begins in the shaft of the bone near the epiphysis. Often it appears that the infection begins in the line of the epiphysis itself and for this reason the term acute epiphysitis is sometimes used. It is the very rich blood supply in growing bone that accounts for this behavior. Sometimes there will have been a preceding trauma with some injury to the epiphyseal line such as partial separation or hemorrhage.

If the point of infection is near the epiphyseal line it may break through the bone at this point and reach the periosteum. If drainage is instituted within a few hours of the onset of the infection recovery may take place before there is much detachment of periosteum or any extensive involvement of the shaft and before the medullary canal is infected. If the infection is massive involving a considerable area of bone the

periosteum will be detached over a large surface and the infection will travel through the bone to the medulla and thence along the medulla.

It is in these severe cases that the full damage to bone is seen—despread necrosis with large areas of detached periosteum and extensive involvement of the medulla. It was thought for a long time that the chief avenue of infection was along the medullary canal but Starr showed that the infection begins in the marrow of the cancellated bone of the metaphysis and that it spreads along the epiphyseal line to the periosteum elevating the periosteum and extending along the surface of the cortex through which it invades the haversian system and reaches the medulla. Therefore the medullary canal instead of being invaded early and acting as the chief avenue of widespread infection is often the last of the bony structures to be invaded. Somewhat later the periosteum is broken through and pus may be found collected in pools in the medulla in the cancellated bone after the periosteum and in the soft tissues outside the periosteum. Extension through the epiphysis into the neighboring joint is much less common than would be expected.

In many of these patients the infecting organism can be recovered from the blood stream. Sometimes the septicemia is overwhelming and death may occur from forty-eight to seventy-two hours after the onset of local symptoms. More often the infection although very rapid and severe causes widespread local destruction of bone and later distant complications develop as a result of blood stream infection such as involvement of another bone suppuration in a distant joint, suppurative pericarditis or empyema. In acute osteomyelitis especially in the severe diffuse type a definite train of events follows the acute process unless early diagnosis and prompt treatment are followed by localization of the infection. Because of severe infection and a starved circulation more or less extensive necrosis of bone takes place. The raised periosteum carrying with it the osteogenic layer soon begins to lay down new bone which surrounds the dead portion of the shaft. The separation of devitalized bone from the living bone is called sequestration and the mass of dead bone is called a sequestrum. Because it is dead the sequestrum becomes an infected foreign body around which suppuration continues and the pus escapes to the surface through openings in the involucrum called cloacae.

Predisposing Factors—Acute osteomyelitis is a disease of the young. Most cases occur in children from two to twelve years of age. There is often no definite history of trauma especially when the disease occurs at or near the junction of the shaft with the epiphysis. Exposure to cold seems to play some part by lowering the local resistance. Boys are affected more often than girls the proportion being three or four to one. The femur, tibia or humerus is usually involved. Most reports give the lower end of the femur the highest incidence but in the writer's ex-

perience the lower end of the tibia has been more often affected. It is sometimes stated that this disease is more common in the late winter and early spring and the writer's experience supports this opinion.

Acute infection of the mandible is common and at times very destructive. The infection reaches the bone along the tooth sockets and may follow almost any dental procedure from extraction to cleansing of the teeth. It may be latent but often is directly introduced by unclean work. Any chronic infection of the skin or mucous membrane may be the source from which emboli enter the blood stream and lodge in the bone.

Clinical Varieties—There is the very acute destructive and extensive infection of all elements of bone confined usually to the shaft. This is the acute diffuse osteomyelitis described by Phemister.

Another type is the so called acute epiphysitis seen in the young in which the infection begins at or near the epiphyseal line and breaks through to the periosteum early. If the diagnosis is quickly made and proper drainage is obtained little involvement of the metaphysis and not much lifting up of periosteum result.

There is also the relatively less acute infection of the bone ends seen in compound fractures or infection of the bone following open reduction with the use of wire plates or nails to fix the fragments. There is also acute localized osteomyelitis confined to a small area of the medulla or of the cancellated bone of the shaft or of the epiphysis. There is a rather sharply localized infection leading to necrosis and suppuration and resembling an abscess in its general behavior. Such an infection is not very severe; it usually causes local pain, tenderness and disability and if neglected may spread more widely. Following drainage if the area of necrosis is large there will often be left a long standing infected sinus leading down to a bone cavity that fills in either very slowly or not at all.

Garre described an acute diffuse sclerosing osteomyelitis in which there is little suppuration but considerable sclerosis with small areas of necrosis. Such an infection almost always becomes chronic and may continue more or less active for years.

Osteomyelitis may begin in the sacrum or vertebrae and bring about a confusing symp-

tomatography. In the early stages roentgenograms are negative the symptoms are those of infection and the signs point to meningitis. Careful spinal puncture may demonstrate the presence of pus between the bony canal and dura and clear fluid in the subdural space. Prompt drainage of the extradural space is indicated. There have been seven cases in the service of Dr. M. C. Pincoffs and his associates with five recoveries and two deaths. Three of these have been reported.

Symptoms.—In acute osteomyelitis the onset is sudden sometimes followed by such rapid progress of the disease that delirium and coma may supervene before localizing signs and symptoms are evident. This is not usually the case but many children are desperately ill from the very beginning of the infection. Sometimes the onset is surprisingly like that of pneumonia beginning with a short period of malaise followed by a chill with high fever, rapid pulse and a sharp elevation of the leukocyte count. The face is florid and there is profuse sweating, restlessness and anxiety. In pneumonia the local signs are in the lungs and in osteomyelitis they are in one or more bones. The outstanding symptom is local pain which is continuous, deep, boring and severe and the outstanding sign is exquisite tenderness on pressure over the bone with increase in discomfort brought out by tapping along the shaft of the affected bone.

In the early stages there will be no involvement of the soft parts outside of the bone. The infection as already indicated usually begins in the end of the shaft close to the epiphysis and the manner of onset, the absence of evident redness and swelling and the nearness of the pain to a joint will usually cause loss of valuable time in arriving at a correct diagnosis. It is unusual for surgeons even in large clinics to see patients with acute osteomyelitis early enough to prevent sequestration and long illness and disability.

In acute cases after twenty-four hours there will often be some edema and tenderness in the soft parts over the end of the involved bone and if the patient is still not treated suppuration will usually develop in the soft tissues adjacent to the bone end. This occurs after the infection has broken through the periosteum.

By this time the patient is very ill with high fever, rapid pulse, dehydration and exhaustion from pain, lack of sleep and infection. Very often there will be vomiting with disturbance in the acid-base balance and often delirium if not coma. The leukocyte count is usually very high.

A careful history often uncovers the presence of predisposing factors as well as possible sources of infection. There may have been some infection of the skin or subcutaneous tissues, a fistulous tract or an ulcer in which case the staphylococcus is suspected or there may be a history of nose or throat infection with involvement of the accessory sinuses, middle ear or mastoid in which instance the streptococcus is apt to be at fault. These patients are usually children and it is sometimes difficult to establish any previous history of trauma or chilling. In many instances blood cultures taken at this time are positive.

There are a number of complications that are likely to occur. A second bone may be involved or there may be extension of infection into a distant joint as in pyemia. Suppurative pericarditis is occasionally seen and may easily be overlooked. If the blood stream becomes infected the symptoms are modified in accordance with the kind of organism that is present. If the septicemia is due to the streptococcus the pathology and symptoms are typical of this infection—very acute and develop rapidly; the fight is not to be won or lost quickly.

If *Staphylococcus aureus* or more rarely *albus* is at fault the progress will be relatively slow with a tendency to multiple joint suppurations, irregular chills and wide variation in the range of temperature with possible suppuration in the serous cavities. This tendency to prolong the pathology and symptoms is seen in any typical case of pyemia; does not improve the prognosis over that of streptococcal septicemia. In both the outlook is unfavorable.

Roentgenograms are of no positive value in the early diagnosis of acute osteomyelitis and negative findings may give a false impression of security. It is not until necrosis begins to be evident in the bone or the periosteum is lifted up that the x-ray picture is of any help, usually from four to seven days elapse before these changes are evident.

In the later stages of acute osteomyelitis the x ray picture is of great value in estimating the amount of necrosis and the progress of sequestration together with the extent and density of the involucrum, but all of this is far removed in time from the onset of the disease.

The early diagnosis of acute osteomyelitis is a matter of great difficulty. Many good clinicians who are keen and prompt in the diagnosis of other acute infectious diseases are often slow in making a diagnosis of acute osteomyelitis. Because of the close proximity to joints the diagnosis of acute infectious arthritis is often made, scurvy is sometimes considered and because a child does not move the affected limb, poliomyelitis is suspected. After the soft parts are involved a diagnosis of rheumatic fever, erysipelas, cellulitis or lymphangitis may be made.

If a child complains of pain over the end of a bone and is loath to move the limb, if there is tenderness on deep pressure over a bone as well as symptoms of an acute infectious process, if the onset of these signs and symptoms has been abrupt and if the evidences of infection are rapidly on the increase a diagnosis of acute osteomyelitis should be made and treatment begun immediately. Any delay invites disaster.

Treatment.—There have been two distinct schools of thought and practice regarding the time factor as applied to the treatment of acute osteomyelitis. One group advocates waiting from five to seven or nine days until the infection has localized and drained into an abscess in the soft parts. Another group is convinced that the infected bone should be drained as soon as possible but believes that the operation should be one of drainage and confined to the area of infected bone.

A number of reports are coming into the literature advocating the waiting method with later drainage especially in children under two years of age. Chemotherapy, bacteriophage vaccines and transfusion together with supportive treatment may limit the operation to the need of drainage of the soft parts only with later resolution without sequestration in a number of instances. The number of surgeons who lean toward this latter more conservative treatment is rapidly

increasing because of recent advances to be discussed in the following paragraphs.

Under the head of *chemotherapy* two very great advances have been made in the treatment of osteomyelitis—the sulfa drugs and penicillin. These two agents are apparently revolutionizing the method of treatment of bone infections. The sulfa drugs were first in the field. In the main sulfanilamide is more useful in the treatment of streptococcus infections while sulfathiazole is a better agent in combating staphylococcus bone infection. Sulfadiazine is apparently almost equally valuable in either streptococcal or staphylococcal infections. This should be the drug of choice when it is impossible to determine the bacterium present.

Until penicillin became more readily available the sulfonamides were widely used in osteomyelitis especially in the acute forms. If treatment was begun early before extensive necrosis of bone or raising up of the periosteum by liquid exudate in a fair number of instances the giving of sufficiently large doses of the sulfonamides under careful blood level checks was followed by absence of either sequestration or extensive bone necrosis although in many instances repeated x ray examinations showed widespread reaction of bone to infection. As in other infections these agents are used either by mouth or intravenously depending upon the acuteness and extent of the infection.

Penicillin has so recently become widely available in civilian hospitals that there are very few reports at hand in which the observations of osteomyelitis have been followed through until final cure of the disease has been effected. Certain it is that this agent is most valuable and efficient in the treatment of osteomyelitis whether acute or chronic, localized or extensive, single or multiple or associated or not associated with a demonstrable blood stream infection. Many surgeons are hopeful that this agent is the solution of the disabling and death dealing disease *acute hematogenous osteomyelitis*.

Our experience however seems to suggest the warning that in some instances at least serious symptoms, blood stream infection and spread of osteomyelitis are kept in check while penicillin is being administered and that when the drug is stopped all of the

cal signs and symptoms recur. Oral administration requires large dosage. The most used avenues of medication are intramuscular and intravenous. In osteomyelitis, when treatment should be continued for a number of days at least, probably the better method of the two is by muscle. This presumably creates a reservoir of the drug whereby the drug is continuously absorbed. Penicillin is excreted rapidly chiefly by the kidneys and in the intramuscular method of administration we give 10 000 units every three hours for an average total of 1 000 000 units which requires something more than twelve days. We give the same dose to children. If the urgency is very great we may do one of two things: either give the drug intravenously by constant drip so that the patient gets from 80 000 to 100 000 units each twenty-four hours or augment the intramuscular method with an initial intravenous dose of 90 000 units. In both avenues penicillin is dissolved in normal salt solution in preference to distilled water as we believe this method is less painful. We have noticed no evidence of shock and very few minor reactions.

If operative intervention is decided upon the problem is one of drainage with as little destruction of bone as possible with as little spread of infection as possible and with the saving of periosteum because it is from the osteogenic layer of the periosteum that most of the repair is to come. The medullary canal is involved later than the cancellous bone and periosteum and should not be opened unless it is already infected since exposing the medulla to infection may lead to extension of the infection along this canal.

If the diagnosis of acute osteomyelitis is reasonably well established the patient should be treated promptly for shock, the dehydration should be combated and the blood stream infection should be treated by transfusion. Chemotherapy may change very materially the treatment of osteomyelitis. There are a number of difficulties in the way at present, however, one of which is the delay in determining the infecting organism and another is the toxic effect of these agents in large doses. Perhaps a single drug efficacious for both staphylococci and streptococci will be speedily available.

If operation is undertaken the infected bone should be exposed care being taken to avoid blood vessels and nerves and not to open tendon sheaths or the synovial membrane of the neighboring joint. If the soft parts are intact an incision should be made through them down on the periosteum. If the periosteum is not involved it should be incised and a small hole drilled into the bone, keeping close to the epiphyseal line in the long bones and making the opening on the side of the metaphysis. Pus is almost always found in the cancellous bone close to the epiphyseal line and at an early stage the medullary canal is not involved. However it is not often that a patient comes to operation so early. More commonly the periosteum is found to be elevated with pus between it and the bone and by that time the medulla is infected and requires drainage. As little damage to the bone as possible should be inflicted. A number of small openings should be made so as to drain the bone and the canal. It is most important not to gouge out bone with a sharp curet and it is equally important not to damage the contents of the medullary canal. Drainage is all that is needed at this stage.

If the patient is young and the epiphyseal line is involved it is most important to safeguard the limb against pathologic epiphyseal separation as this mishap causes deformity and complicates the entire problem of treatment and convalescence.

Probably the best method of supporting an ill patient through the first few weeks of acute osteomyelitis is by means of repeated small blood transfusions. Many reports indicate that this procedure often seems to turn the balance in favor of recovery.

Treatment does not end with drainage of the infected bone. The limb must be safeguarded and cared for and the patient treated through a long convalescence. Support of the damaged limb is essential and repeated dressings have many disadvantages. The Orr method or some modification of it will meet most of these requirements. The length of time that elapses before recovery is complete varies from a few weeks to many years; this is determined by a number of factors, by far the most important of which is early diagnosis followed by prompt and efficient drainage. If physicians were as keen in dealing with

this condition as they are in most other fields the story would be a different one

ARTHUR M. SHIPLEY

CHRONIC OSTEOMYELITIS

Chronic osteomyelitis is one of the great trials of surgery. As a result of late diagnosis most patients with acute osteomyelitis become victims of chronic bone infection. There are many problems that must be met and combated. It is a long and disabling malady which causes great economic loss because of hospitalization, nursing and home care which interferes seriously with the child's education and in the adult results in an extended period of inability to work. These circumstances together with deformity and the likelihood of complications make this disease a major disaster fraught with anxiety for all concerned.

Pathology and Course—If only one epiphyseal line is destroyed in a child the growth of that bone may be satisfactory provided the infection is checked and controlled. Fracture or epiphyseal separation during the early stages of chronicity before the involucrum is solid may occur. Unless continuous care is taken there will be deforming contractures of neighboring joints. The slowly healing granulation tissue is apt to be the avenue for repeated infections some of which may be severe—erysipelas, cellulitis or tetanus. Even after the open wound is healed the scar is thin, adherent and easily injured. Many patients with old osteomyelitis have recurrent attacks during which there is a lighting up of the infection. Months or years after apparent quiescence and healing a fresh infection breaks out either at or close to the original disease or in a distant bone. Epidermoid carcinoma may develop in the scar (Marjolin's ulcer).

If suppurative arthritis complicates the bone infection, more or less ankylosis is apt to occur and unless care is taken the joint will become fixed in an unsatisfactory position which will require some type of joint repair or corrective osteotomy. These chronically infected persons suffer the effects of lowered resistance and fall an easy prey to almost any malady. Added to all this a chronically disabled person may develop some type of insufficient personality and

even after being returned to fairly normal health may be unable or unwilling to carry on.

Chronic osteomyelitis may occur without preceding acute damage. The infection may begin as a subacute process in bone due to *B. typhosus*, a complication of typhoid fever which appears late in the illness or long after the patient is apparently recovered. The ribs are a favorite site for this infection. Local application of typhoid vaccine is helpful in the treatment. A localized chronic bone infection for example *Brodie's abscess* may occur without previous acute osteomyelitis and is due usually to a staphylococcus. Localized chronic collections of pus in bone however are very commonly seen as a late occurrence in hematogenous osteomyelitis. These areas of necrosis are due to latent infection and may be seen for months or years after the original infection has apparently healed.

Just where the dividing line in time between acute and chronic osteomyelitis is placed depends largely on the individual surgeon. Certainly in most cases of osteomyelitis when first operated on the patient is already in the early stage of chronicity that is the operator knows that the patient will require adequate drainage, immobilization, safeguarding against reinfection and all possible supportive measures because the condition is certain to be long drawn out involving necrosis, elimination and repair. These changes must take place in bone where most changes take place slowly so that progress is measured in months and years instead of in days and weeks as in many soft tissues.

Treatment—Chronic osteomyelitis is at best an unsatisfactory and disappointing disease to treat. Failure to effect a cure has led to the trial of a number of procedures and one is confused rather than encouraged by reading the literature. The care of a patient with chronic osteomyelitis is a serious problem. There is the expense and trouble of repeated dressings, the exposed area is repeatedly reinfected, there is the risk of distant complications and the bone at the site of infection may suffer a pathologic fracture. In children joint contractures are liable to occur. The long convalescence during which there is more or less absorption of toxins is

a heavy physical strain and the mental attitude of the patient is apt to be most unhappy. The sulfonamides and penicillin are much used in chronic osteomyelitis, often with excellent results provided sequestra are removed and collections of pus drained.

The pathology during the acute stage is a determining factor—the extent of the stripping up of periosteum, the length of the medullary canal invaded and the amount of bone infected. If there is complete sequestration with rapid formation of involucrum, the generally accepted method of treatment is to safeguard the bone from pathologic fracture and the neighboring joints from contracture, to see that drainage is ample and to wait until the sequestrum is completely separated and the involucrum reasonably firm in the meantime, riding the reparative mechanisms by every means available—tranfusions, open air, sunlight, proper food, tonics, good nursing, care, etc.

After sequestration is complete and the involucrum sufficiently firm to take over some of the functions of the dead bone, sequestrectomy is indicated. This type of late operation in osteomyelitis in the chronic stage should be done with care and precision. The loss of blood is sometimes alarming and is always a factor to be considered. If possible the actual operating should be done with a tourniquet placed above the operative field. Great care should be taken to disturb the involucrum as little as possible and the periosteum should be saved to the fullest extent because the osteoblasts are essential to the formation of new bone. Whichever clamping must be done in order to release the sequestrum or to insure better drainage care should be taken to destroy as little good bone as possible because wherever fresh bone is exposed to infection a new process of bone necrosis is set up and there is another long wait for sequestration to occur.

Regarding the operation itself there are two schools of attack—the radical and the conservative, each can point to victories and both have suffered defeats. The conservatives limit early operating to securing and maintaining drainage with the least possible removal of bone until sequestration is complete. The more radical operators remove considerable areas of infected bone, make a gutter of the entire length of the involved

shaft and leave the wound in the overlying soft parts wide open. This produces a large heavily infected area and it is difficult to prevent reinfection and to get rid of necrotic tissue. Complete subperiosteal resection of the entire area of infected bone has been practiced but this causes a long period with little bony support while the involucrum is forming. There are several distinctly different methods of dealing with these cases and each has outstanding advantages.

If it becomes necessary to open and drain infected bone, the Orr method overcomes many of the dangers and difficulties of repeated dressings at short intervals. Briefly, his method may be described as follows: The limb is immobilized on a traction table and the infected bone is opened for adequate drainage. The wound is opened widely both in the bone and in the soft parts. The entire wound is filled with a vaselin gauze pack which projects over the wound edges and is covered by a dry absorbent dressing. The limb is then immobilized in plaster, the cast should be snug and extensive enough to control muscle spasm and prevent pathologic fracture and joint contractures. These dressings may be left undisturbed for from four to eight weeks.

The writer has followed this plan and found it very efficient. The one objection is the odor from the unchanged dressings continuing the wound discharge. The cast may be changed oftener than Orr advocates but when the amount of discharge becomes less the odor also is less in evidence. Certainly the infection in the soft parts clears up very rapidly and the patient in the meantime is comfortable. He is also saved the expense and pain and risk of daily dressings. The greatest advantages are the relative freedom from reinfection of the wound and the absence of the destruction of the elements of repair brought about by the trauma of repeated dressings. Bacteriophage, chemotherapy and vaccines are at times helpful.

Chronic osteomyelitis is often seen as a complication of compound fractures especially in comminuted fractures where there has been extensive exposure of overlying soft parts to infection and where early excision of the wound has been carelessly done. When chronic bone infection is established the treatment is usually largely ex-

pectant. The fracture is adequately treated so as to overcome overriding, angulation and rotation and the infected area is drained just enough to allow the free escape of infected and necrotic material. Some of the bone usually becomes separated and requires removal, usually causing delayed union. The utmost patience plus drainage with immobilization will in most instances insure a good although considerably delayed result. The untoward factors are chronicity, atrophy of unused muscles and stiffness in the immobilized joints and these unsatisfactory end results are in direct ratio to the duration of the convalescence and the age of the patient. In comminuted compound fractures followed by infection, bone fragments may become completely loose in the tissues and will be the chief cause of persistent sinuses until removed.

ARTHUR M. SHIPLEY

TUMORS OF BONE

The variable aspects of tumors of bone often make it difficult to decide on the diagnosis and the form of treatment. The age of the patient, the duration of symptoms, the number of bones affected and the roentgenograms are of importance in making a decision. In patients under ten years of age the most frequent solitary tumor is a bone cyst (usually in the upper part of the humerus) and Ewing's sarcoma (most often in the shaft of the femur or tibia). Christian's disease of bone or some metabolic deficiency such as rickets or scurvy is one of the commoner multiple skeletal diseases of childhood.

The symptoms of pain and swelling extend over a period of several weeks or months in cases of bone tumor. On the other hand, in osteomyelitis, nontumorous symptoms may develop within a few days. When the history of a bone tumor dates back several years, some unusual complication must be present.

Multiple tumors of bone are usually benign in children and malignant in adults. Among the multiple tumors of adults, the benign condition, diffuse osteitis fibrosa with hyperparathyroidism, must be borne in mind as a possibility, although the probabilities may favor metastatic carcinoma.

In the interpretation of the roentgenogram it is well to have for examination both anteroposterior and lateral views and when feasible a roentgenogram of the opposite normal bone for comparison. Where there are multiple foci of involvement in a single bone, roentgenograms of the pelvis, skull and chest should be made. Malignant tumors of bone are prone to invade all of the regions or zones depicted in the film. Bone destruction or bone production or both will invade the marrow cavity, the cortex, the periosteal region and the overlying soft parts. Benign tumors are most often limited to a medullary, cortical or subperiosteal origin. When bending deformity is seen in the affected bone, it is an important sign of benignity.

The Wassermann reaction and the leukocyte count are always important. In rare instances the diagnosis may depend on blood calcium and phosphorus determinations or estimation of the total plasma proteins or on examination of the urine for Benec-Jones bodies.

Biopsy of bone is a safe and valuable procedure when competently done and amputation should not be performed without confirming the diagnosis by this method.

The microscopic features of bone tumors cannot be adequately interpreted without reference to normal histogenesis. In the skeletal tissues, three phases of osteogenesis exist with corresponding tumor formations. In the most primitive, the cycle of development passes from precartilaginous connective tissue through fetal and adult cartilage to the calcified state. To this fibrocartilaginous series belong chondrosarcomas, chondroblastic sarcomas, chondromas and osteochondromas. Following calcification, a resorptive phase appears in bone characterized by proliferation of giant cell osteoclasts. To this series of changes belong the growths known as giant cell tumors, solitary bone cysts (a regressive or healing phase of giant cell tumor) and multiple cystic diseases known as von Recklinghausen's osteitis fibrosa cystica. Finally, there are the steps passing from connective tissue through osteoblasts to bone, resulting in true bone formation which may be termed the fibroosseous series. In the membranous bones, this is the only series of developmental changes observed. To these phases belong sclerosing

and osteolytic osteogenic sarcomas, as well as osteomas of the jaw and skull bones.

CLASSIFICATION OF BONE TUMORS

1 Tumors of Osseous Origin

Fibrocartilaginous	Resorptive series	Fibro-osseous series
Osteochondroma Chondroma Chondroblastic sarcoma Chondrosarcoma	Giant cell tumor Bone cyst Diffuse osteitis fibrosa	Osteomas of skull and jaws Sclerosing sarcoma Osteolytic sarcoma

2 Tumors of Non Osseous Origin

Marrow and haversian systems	Metastatic deposits	Invasion by direct extension
Ewing's endothelial myeloma Multiple myeloma	Carcinoma of prostate breast kidney etc	Fascial sarcoma Neurogenic sarcoma etc

fracture Re-section rather than amputation will often suffice for radical removal of a tumor in a bone of the arm or in the fibula The value of irradiation in reducing the size of the tumor or in relieving pain in Ewing's

Osteochondroma—The most common tumors of bone are the benign osteochondromas These tumors often referred to as exostoses produce bony outgrowths near the ends of the long bones which are exaggera-

Fig 284—Roentgenograms showing two views of an osteochondroma in a boy of fifteen years at the site of the adductor tubercle in the lower femur The features of the growth depicted in these roentgenograms are typical

sarcoma multiple myeloma and metastatic carcinoma must be borne in mind as well as its usefulness in accomplishing a cure for such conditions as inguina and giant cell tumors Chondroblastic and osteolytic sar-

tions of normal bony protuberances forming the attachments for important ligaments and tendons Although such growths are commonly discovered in young adults under twenty five, the tumors in most instances

grow during adolescence from a congenital focus. Osteochondromas resulting from trauma are rare. Gradual growth unaccompanied by severe symptoms is the rule. Mild pain, stiffness or swelling alone is present, and many of these cases are accidentally discovered on roentgenographic examination. The tumor is hard, nodular and fixed to the underlying bone. The x-ray picture shows a cauliflower like mass with a lobulated translucent top and beneath an osseous pedicle or base which fuses with normal cortical and cancellous bone (Fig 281). Calcified particles stipple the periphery of the

Fig 283—A benign osteoma of the skull in an adult which was preceded by trauma. The roentgenogram depicts an intact inner table and an outward proliferation of radiating spicules which elevate the periosteum. The bone formation is occurring directly in fibrous tissue.

lesion, and in rare instances a bursal sac with fluid and calcareous material forms. Under the microscope the outermost layer of the growth shows strands of primitive connective tissue (encapsulating and dipping into the underlying cartilage). Proceeding from this capsule to the osseous base in their order of appearance are zones of fetal, adult and calcifying cartilage, newly formed bone and adult spicules interspersed with fatty marrow.

Osteochondromas are rare outside of the long bones and pelvis. An occasional one is found at the occiput, in the spine or in the

scapula. The maximum diameter of the lesion varies between 2 and 8 cm., and the growth proceeds slowly to final arrest at about the age of twenty-five. These are important features in the diagnosis. Osteomas occurring in the frontal bone, the jaw or the sinuses show ossification in fibrous tissue and do not contain cartilage (Fig. 285). They may grow rapidly but do not undergo malignant change. They have an age incidence similar to osteochondromas. Sometimes these growths of membranous bone follow trauma and during active development contain a cellular fibrous stroma (so-called ossifying fibromas) and may be erroneously classed as fibro-sarcomas. These more cellular tumors may appear in childhood. Osteophytes seen in arthritis have a similar distribution to osteochondromas but occur more often in elderly adults. They are small (rarely exceed 1 cm. in their greatest dimension) and are usually multiple on either side of the joint. Osteochondromas which in adults grow rapidly and exceed the size of an adult fist must be regarded with suspicion and have usually undergone malignant change.

A single osteochondroma of moderate size with slow growth and few symptoms may be left untreated. It is well to have an x-ray examination to check the growth every year or so after the age of thirty. Simple excision may be performed for the osteochondromas which produce pain or dysfunction. Osteochondromas are not influenced by irradiation.

Multiple Exostoses—One or more simple osteochondromas may occur in a long bone without distorting the entire extremity. This, however, is rare. When more than one such growth is depicted in the roentgenogram, there are usually similar growths elsewhere accompanied by cartilaginous lesions within the cancellous spaces. Numerous deformities throughout the entire skeleton result from multiple growths of this type. This condition is congenital in origin, and frequently several members of the same family running through more than one generation are affected. This combination of exostoses and enchondromas is referred to as hereditary, deforming chondrodysplasia and sometimes as Ollier's disease. All the bones derived from cartilage may be affected. Bowing of the arms and legs occurs. Symptoms may result from impingement by one or

more bony outgrowths on important vessels or nerves. The family history aids in making the diagnosis. Adequate roentgen studies permit ready diagnosis. Prolonged osseous extensions proceed outward from the bones in the direction of the muscle pull. The metaphyseal regions where these protrusions arise are widened so that the ends of the bones have a broad rectangular appearance. In the region of the osteochondromas and particularly in the small bones of the hands and feet are cartilaginous defects, visible as areas of rarefaction (Fig 286). As in single exostoses the symptoms progress until skeletal growth normally ceases, at about the age of twenty-two.

Pathologically the exostoses have the same appearance as that described for single osteochondromas. The central chondromas are identical with those described below.

The prognosis as far as life is concerned in these cases is good. After the age of twenty-two (or before if imperative), the

adults are contraindicated at this site because of the tendency of these foci to undergo malignant change following such intervention. Sarcoma may rarely supervene in these osteochondromatous growths in adults without obvious provocation.

Fig 287—Roentgenogram of a large central chondroma of congenital origin occurring in a long bone. The defect shows longitudinal streaking fraying of the cortex and calcareous stippling typical of chondroma (for typical benign enchondromas of the phalanges see previous figure).

most pronounced growths which produce symptoms may be excised. The other deformities usually do not warrant an attempt at correction. If cartilaginous tissue appears within the marrow of the bone in the region of the deformity, corrective procedures in

Benign Chondroma—Benign chondromas, chondromyxomas, or enchondromas occur centrally in the small bones of the hands or feet and are occasionally seen in the spine, in the ribs, or in the sternum. Other sites are exceedingly rare. Usually a phalanx of a finger in an adult is affected. Expansion and thinning of the cortex occurs with a mild degree of pain. There may be a pathologic fracture. In the roentgenogram a characteristic central translucent area is depicted. A frayed shell of bone overlies the central mass, which is traversed by one or more longitudinal trabeculae (Fig 287). Small dense calcareous particles are usually visible in the tumor. When the presence of a solitary chondroma is suspected in any bone outside of the phalanges or metacarpals, roentgenograms should also be made of the hands and feet. Occasionally, these will show longitudinal areas of rarefaction with irregularities of the overlying cortex, indicating

the presence of congenital cartilaginous rests. Under the microscope lobules of adult cartilage are found at the center of the growth. Toward the periphery there are one or more strands of connective tissue accompanied by fetal cartilage or myxomatous tissue. Histologically the small chondromas situated in the carpal or tarsal bones or in the phalanges are more cellular than the larger growths found in the sternum and spine or in the shaft of the long bones (Fig 288). Nevertheless chondromas of the small bones of the hand or foot (exclusive of the os calcis and astragalus) may be cured by thorough

pathologic fracture is the first indication of the presence of the disease. Mild pain or dysfunction running a chronic course over a period of two or more years may be elicited in taking a careful history. When roentgenograms are made a central defect appears in the film surrounded by an intact and symmetrically expanded cortex (Fig 289). The cavity in the bone is traversed by irregular trabeculae of dense fibrous tissue. When a pathologic fracture is present signs of re-ossification are seen. Exploration discloses a cyst containing fluid enclosed by a wall of osseous and fibrous tissue. Under the micro-

Below in the region of the lower shell is cellular pre-osteoblastic connective tissue. Despite the cellularity of such tissue chondrocytes are located. The small bones are benign and may be cured by curettage.

excision or curettage followed by cauterization with 50 per cent zinc chloride. On the other hand it is extremely dangerous to remove cartilaginous growths of the larger bones unless the entire area can be safely resected. In these larger bones the tumor will recur rapidly, will transplant in the surrounding tissues and will eventually metastasize if incompletely excised. These growths are not radiosensitive.

Benign Bone Cyst.—In children under fifteen years of age a benign bone cyst occurring in the upper metaphysis of the humerus, femur or tibia is one of the commonest tumors of the bone. Frequently

scope the proliferation of connective tissue and new bone formation suggests a healing reaction. Smaller cavities when present contain the remains of old hemorrhage and a sprinkling of large giant cells. Cysts with such multilocular cavities are termed poly-cystic osteitis fibrosa.

Cysts immediately adjacent to the epiphyseal line on the shaft side which have been present for less than a year show an even greater amount of vascularity and more numerous giant cells than are seen in poly-cystic osteitis fibrosa. These giant cell variants of bone cysts are to be distinguished from true giant cell tumor by their occur-

rence on the shaft side of the epiphysis in patients under twenty. The prognosis is far better than in a case of typical giant cell tumor, and the patient will respond more readily to deep x-ray therapy (Fig 289 a, b and c).

Arrest in the growth of a bone cyst without complete healing and obliteration of the cavity is accountable for the latent bone cyst seen in adults. These latent cysts are symptomless and are usually found incidentally in a routine x-ray examination.

A typical bone cyst discovered in the shaft of a long bone of a child as a result of pathologic fracture may be treated by simple splinting until reossification and healing are secured. Recurrence may take place but may also follow simple curettage. If the lesion is explored the lining should be stripped, the shell of bone crushed and the cavity obliterated with bone chips. The giant cell variant of the bone cyst responds well to deep x-ray therapy in moderate dosage. Latent bone cysts in adults usually require no treatment.

Brodie's abscess, which occurs most often in the tibia of young adults producing a central defect of small size may be mistaken for a bone cyst. The cortex, however, is not thinned and expanded after the fashion of a cyst but instead is thickened by periosteal reaction which is accompanied by pain, tenderness and the symptoms of low grade inflammation. Benign angiomas of bone usually produce irregular multilocular cysts with thinning of the cortical area. They do not produce the symmetrical oval defect seen in cases of bone cysts. A common site for angiomas is in the vertebrae. Rarely an osteolytic sarcoma may erode the bone and suggest a cyst. Again the lesion is usually asymmetrical and a periosteal reaction so called hipping, overlies the central defect.

Diffuse Osteitis Fibrosa (von Recklinghausen's Disease)—While the term *osteitis fibrosa* is loosely used to refer to all types of cysts of the bone, there is now a tendency to restrict this term to a diffuse disease of the skeleton accompanied by adenoma or hyperfunction of the parathyroid glands. In such cases the fundamental disturbance is a supersaturation of the blood serum with calcium, increased calcium excretion and a generalized demineralization of the bones.

The blood calcium level may be elevated to from 13 to 20 mg. and the phosphorus lowered to 1 or 1.5 mg. per hundred cubic centimeters. In isolated areas the rarified bones show localized cyst formation and occasionally giant cell tumors. In the x-ray examination the diagnosis depends on evidence of diffuse osteoporosis, bending deformities and globular areas of cysts or tumor formation (Fig 290). Treatment is directed at a reduction of the parathyroid hormone output and remineralization of the skeleton. The para-

The healed lesion in August 1935, eighteen months after the last treatment.

thyroids may be explored and the adenoma surgically removed or hyperfunction may be checked by irradiation over the parathyroids. The patient should be placed on a high calcium and phosphorus diet plus vitamin D. In the diagnosis of this diffuse skeletal disease determinations of the blood calcium and phosphorus values and also of the blood phosphatase value (which is elevated), estimations of the urinary excretion of calcium and demonstration of parathormone in the blood stream by the Hamilton rabbit test are important. If proper laboratory tests

of this character are carried out, confusion of this condition with metastatic carcinoma or multiple myeloma should not occur.

long bones. In the x-ray picture the tumor produces a more or less circular defect, asym- metrically situated in the epiphysis, over-

Fig 200.—Roentgenogram of the pelvis in a case of von Recklinghausen's osteitis fibrosa cystica associated with hyperparathyroidism. Osteoporosis, bending deformity and cyst formation are characteristic of the disease.

Giant Cell Tumor.—Adults, usually between twenty and thirty years of age, may have a tumor of bone which produces a globular area of rarefaction in the epiphysis of

laid by a thin shell of bone, which is usually perforated at one or more points (Fig. 201 a and b). If the tumor persists without treatment for a period of more than fourteen months after the onset of symptoms, extension into the soft parts is the rule. Under a microscope many large multinucleated cells are seen embedded in a highly vascular stroma with small round and spindle cells (Fig. 202). Histogenetically, the tumor is related to the resorption of calcified cartilage by giant cells, which occurs as a step in normal growth of bone in the region of the epiphysis until late in life. Healed giant cell tumors (following irradiation) show the formation of a typical bone cyst. This and other pathologic considerations indicate that the bone cyst and giant cell tumor are closely related lesions (the two may coexist in von Recklinghausen's disease of the bones).

In the first two decades of the present century, the standard treatment for giant cell tumor was curettage followed by chemical (50 per cent zinc chloride) or thermal cauterization. Satisfactory results were obtained in about 70 per cent of cases. About a decade ago, irradiation was introduced as a method of treatment. Deep x-ray therapy administered over a period of from twelve to twenty-four months results in satisfactory re-ossifi-

Fig 201.—Early roentgenograms of a giant cell tumor in the lower end of the femur. The globular defect has a typical asymmetrical location in the epiphysis of an adult.

the lower femur, upper tibia or lower radius. There is a history of trauma, pain, swelling and pathologic fracture—the typical clinical picture of benign giant cell tumor of the

eration in some instances. Since this treatment does not afford microscopic confirmation of the diagnosis, sarcoma may masquerade under the diagnosis of giant cell tumor. Moreover, repeated courses of irradiation over a period of one or more years may result in malignant transformation with the development of osteogenic sarcoma at the tumor site. Such errors in diagnosis coupled with the long period required to achieve good results with irradiation and the occasional contractures about the joints have brought back into favor the original method of curettage advocated by Bloodgood. Recurrent giant cell tumor in the ulna, fibula or radius should be resected.

Extraskeletal Giant Cell Tumors.—A lesion similar pathologically to the benign giant cell tumor that occurs about deciduous teeth on the gums is known as giant cell epulis. Tumors of this type are seen in children or in young adults and are related to the normal loosening of the roots of the milk teeth by odontoclasts. Their treatment is similar to that just described for giant cell tumor, namely curettage and cauterization. Xanthomas of the tendon sheath or the synovial tissue of the joints often show numerous giant cells and are closely related to the group of tumors under discussion. Their origin is probably related to the embryonic focus in the joint or the adult site in the tendon where sesamoid bones which are derived from fibrocartilage are found.

Ewing's Sarcoma or Endothelial Myeloma.—Ewing's tumor is a neoplasm occurring in the first two decades of life which involves most frequently the shaft of the tibia or femur and which may ultimately metastasize to other bones. The disease never primarily involves an epiphysis. It shows the usual malignant symptoms for sarcoma of bone—pain and tumor followed by dysfunction extending over a period averaging thirteen months and may give the systemic reactions of fever and leukocytosis. In the roentgenogram the disease is first seen to widen the shaft of the bone by stimulating new bone formation in parallel layers in the endosteum and subperiosteum, the latter being raised in parallel onion peel fashion (Fig. 203 a and b). Later the tumor which arises intracortically produces areas of bone destruction in the medullary cavity and sub-

sequently in the cortex. Bone of tumor origin is not formed but fine radiating osseous spicules resembling groomed whiskers may be stimulated in the subperiosteal zone. Histologically the tumor consists of small round cells with dense nuclei resembling lymphocytes (Fig. 204) and apparently arises from the lymphatics of the Haversian system.

In a case of suspected Ewing's sarcoma, deep x-ray therapy should be the first step in the treatment. Rapid shrinkage of the tumor confirms the clinical and roentgenologic diagnosis. Following the maximal effects

Fig. 204.—Photomicrograph of a typical giant cell tumor from the case shown in the previous figure.

achieved by irradiation either resection or amputation should be performed. When such treatment cannot be applied, as in bones of the pelvis, spine or skull, subsequent courses of irradiation should be given. The same type of treatment may be used for Ewing's sarcoma of the upper femur since amputation will not effect a cure at this level. Irradiation alone rarely suffices to cure this disease. On the other hand, combined irradiation and surgical treatment have yielded slightly more than 10 per cent of five year cures.

Garre's non-suppurating osteitis affects

the shaft of the long bones in a manner closely simulating that of Ewing's sarcoma

it is rare. Rapid changes are not seen under deep x-ray therapy, hence this is the most

Fig 903—Roentgenograms of Ewing's sarcoma in the upper portion of the humerus *a* January 1933, before radiation showing wing-like projection of the cortex and pitting of the periosteum; *b* on "onion peel" basis on September 1933 after deep roentgen therapy. The patient has continued to be well (1939).

Fig 904—Photomicrograph showing the fibrous stroma and small round cells resembling lymphocytes seen in typical Ewing's sarcoma.

In this benign condition the new bone that is produced is denser, the periosteum is not split in the characteristic onion peel fashion and destruction of bone in the marrow cavity

reliable method of making a differential diagnosis.

In children under five years of age longitudinal streaking in several long bones with

a periosteal reaction overlying the lesion may be produced by lymphatic leukemia. In such cases the total leukocyte count may be low but the percentage of lymphocytes is usually over 80. It is well before treating a young patient with Ewing's sarcoma to have roentgenograms made of other long bones and a careful differential count made of the white blood cells. Christian's disease and syphilis of the bone may also simulate Ewing's sarcoma in the young. This makes a Wassermann reaction imperative, a rule never to be broken in the treatment of bone tumors. Christian's disease often produces large defects in the membranous bones of the skull. It may however give initial manifestations in the long bones which closely simulate Ewing's tumor. It likewise responds to irradiation. The diagnosis depends on thorough x-ray studies of the entire skeleton and on biopsy in doubtful cases. Under the microscope Christian's disease is characterized by numerous eosinophils, large macrophages simulating Dorothy Reed cell and sometimes by foamy or xanthoma cells. The predominating tissue is lymphoid in type resembling that seen in Ewing's sarcoma and congenital syphilis.

Multiple Myeloma—This rare and fatal condition as the name implies produces extensive involvement of the skeleton. The systemic manifestations are equally widespread. Multiple foci of destruction are found in adults usually limited in distribution to the red bone marrow. Rheumatic pains of increasing severity usually in the back or lower limbs, discovery of a tumor by the patient, sharp pains following exertion, fracture after injury and general weakness with anemia are the cardinal features marking the onset of the malady. As the disease progresses gradual collapse of the spine permits the lower ribs to sink to the pelvic brim giving a characteristic habitus. The patients stand with protruding abdomen, flaring ribs, shoulders braced back and feet widely apart to assist in standing. The chin is thrust forward and may sink to the chest. Involvement of the spine and ribs is accompanied by radiculitis, paraplegia and emphysema of the lungs. A nephrosis with non-protein nitrogen retention and low blood pressure associated with an albuminous substance in the urine known as Bence-

Jones bodies is present in from 60 to 70 per cent of the cases. The plasma proteins may be markedly increased.

Röntgen examination of the tumors reveals areas of bone destruction which appear as multiple punched-out defects varying in size from that of a pea to that of an orange (Fig. 295). Pathologic fracture occurs in 62 per cent of the cases, a rib being most often affected. Microscopic study shows that the tumors are composed of plasma-like cells each with an eccentric nucleus containing a spoke-like arrangement of chromatin. There is a very scanty amount of stroma.

The average duration of life after the recognition of the disease is two years. In rare cases a patient may survive the five year period. Röntgen irradiation which al-

Fig. 295.—Roentgenogram showing the multiple punched-out areas of the skull of multiple myeloma.

leviates the symptoms and may prolong life is the most valuable mode of therapy. The degree of anemia present determines the prognosis.

Multiple myeloma must be distinguished from metastatic carcinoma with multiple foci in the bones and osteitis fibrosa with hyperparathyroidism. The widespread occurrence of small sharply demarcated defects in the marrow cavity unaccompanied by bending deformity or the formation of new bone is the cardinal feature in the roentgenologic diagnosis of multiple myeloma. The fact that a verified case of multiple myeloma has not been reported in childhood is important in the differential diagnosis. Marked anemia, Bence-Jones bodies in the urine and an elevation of the plasma pro-

teas are characteristic laboratory findings which are not found in metastatic carcinoma* or osteitis fibrosa

A solitary focus of multiple myeloma may be the only manifestation discovered by a thorough x ray examination early in the disease. More rarely patients finally die without having any other areas of bone involvement develop. Such cases of multiple myeloma with a solitary lesion must not be confused with the term solitary myeloma commonly used in England to mean benign giant cell tumor

Fig 296—Roentgenogram of a primary chondrosarcoma showing the faintly radiating calcified lines and the translucent soft part space for the peripheral space which is characteristic of the disease

Chloroma is an exceedingly rare form of bone disease usually involving the bones about the orbit and occurring about at puberty. In this disease which has a clinical course similar to that of multiple myeloma there is a leukemic blood picture

Primary Chondrosarcoma—Osteogenic sarcoma containing cartilage may arise after the thirtieth year of life in a patient with benign exostosis or chondroma. Many of these malignant cartilaginous tumors how-

* In rare instances Bence-Jones bodies have been found in cases of leukemia and of metastatic carcinoma

ever are primary in origin and occur periossally in young patients at the site where tendons insert directly into bone. They are most common in patients between the ages of fourteen and twenty-one years and usually are located on the abductor tubercle in the lower femur or on the tuberosity of the upper tibia. The symptomatology is brief, about six months in duration, and is characterized by pain, tumor formation and dysfunction. In the roentgenogram is seen a faint translucent shadow which apparently lifts the periosteum. This wedge-shaped shadow between the cortex and the elevated periosteum is referred to as *lifting* and is an important diagnostic finding (Fig 296). The periosteum is stripped both at the site of the tumor and above and below and lays down a few radiating spicules of calcification and slight amounts of new bone. Involvement of the cortex or the medullary cavity may be extremely slight in primary chondrosarcoma early in the disease, although ultimately this region of the bone is eroded. This is an unusually malignant form of tumor. It is not radiosensitive and is cured by amputation in only about 10 per cent of cases. Microscopically it is seen to be composed of cartilage which is undergoing degeneration accompanied by slight ossification and numerous strands of cellular precartilaginous connective tissue (Fig 297).

Osteogenic sarcoma containing cartilage belongs clinically to the same group as the extremely malignant grades of sclerosing osteogenic sarcoma. In rapidly growing sclerosing sarcoma small amounts of cartilage are found microscopically and the tumor early in the course of the disease may not cast a dense shadow on the x ray film. Such tumors tend to invade the marrow cavity earlier than the pure primary chondrosarcomas. In another extremely malignant grade of sclerosing periosteal sarcoma the varying amounts of osteoid tissue are intermingled with a mixture of osteoblasts and pre-osteous fibrous tissue which under the microscope resemble the osteolytic forms of sarcoma found in the marrow cavity which will be discussed subsequently. By some authors the entire group is referred to as the periosteal group of osteogenic sarcomas.

Secondary Chondrosarcoma—This form of sarcoma confined to adults may super-

venous in benign exostosis, benign chondroma or multiple skeletal diseases, such as Paget's osteitis deformans or hereditary deforming chondrodysplasia. The distribution of these growths differs from that of primary chondrosarcoma in that the upper humerus, pelvis, ribs and heel are more often the regions affected. The duration of symptoms is extremely variable. There may be deformity, rheumatic pains or pre-existing tumor antedating the acute symptoms by five to twenty-five years. When a previous osteochondroma is implicated, roentgenograms show that the original lesion remains in the form of the widened metaphyseal region or as a

change. Some of these secondary sarcomas were described originally by Bloodgood as being pure myxomas of bone. They are not to be confused with benign myxochondromas of the phalanges, which do not undergo malignant change.

Secondary chondrosarcomas are cured by radical excision in approximately one fourth of the cases. The lesions are radioresistant.

Sclerosing Osteogenic Sarcoma.—Sclerosing osteogenic sarcoma is a malignant proliferation of ossifying connective tissue in the subperiosteal and subcortical regions of the metaphysis, often at puberty. The lower femur and upper tibia are the most common

Fig. 297.—Photomicrograph showing clusters of small spindle cells (precartilaginous connective tissue), fetal cartilage cells and irregular calcification in a hyaline matrix typical of primary chondrosarcoma.

protruding ossified base or pedicle. Above there will be a granular infiltrating periosteal shadow, eroding the benign lesion from above downward. In advanced cases the entire tumor site is the seat of an infiltrating mass with scattered osseous debris which penetrates the marrow cavity and leads to pathologic fracture. The secondary nature of the growth is easy to establish when the skeleton is diffusely involved by a pre-existing benign condition such as multiple exostoses or Paget's osteitis deformans.

Histologically, there are cartilaginous masses interspersed with calcified and osseous material and large amounts of connective tissue with evidence of myxomatous

sites. The disease runs a fairly acute course with pain, tumor and dysfunction, perhaps preceded by trauma. The average duration of symptoms is ten months. In the roentgenogram the dense spicules of new bone radiating out in a sun-ray fashion are a characteristic feature (Fig. 298). Immediately beneath this, the bone substance is sclerosed by the infiltration of tumor tissue. In some early cases of sclerosing sarcoma, increased density in the marrow cavity is the first evidence of the disease in the roentgenograms.

The neoplasm is an exaggeration of the function of osteogenesis; hence the gross specimens show osteoid substance and bone often of extreme density stripping the peri-

osteum, extending into the soft parts, penetrating the cortex and invading the marrow cavity. Microscopically, a proliferation of malignant osteoblasts is seen dispersed in a disorderly fashion among immature islands of osteoid tissue. Irregular bone spicules are outstanding. Here and there a small island of cartilaginous tissue recalls the fact that the periosteum from which the growth arises has differentiated from pre-existing perichondrium.

pable mass within six weeks following injury. The ossified tumor shows a wedge of bone that is laminated and separated from the shaft by an interval of soft parts. The marrow cavity and cortex are undisturbed. In sarcoma of bone, all the various zones are affected, including the soft parts, periosteum, cortex and marrow cavity. Acute osteomyelitis may give indications of a previous skin infection. The symptoms are present for a number of days rather than weeks, as in sar-

Fig 298

Fig 299

Fig 298—Roentgenogram of typical sclerosing sarcoma of bone occurring in a boy of fifteen who had had symptoms of pain and swelling for six weeks.

Fig 299—Roentgenogram of a chondroblastic sarcoma arising at the epiphyseal line and invading the shaft of the femur in a boy of sixteen years. There is a definite periosteal reaction. The lesion was curetted twice, and finally the leg was amputated. The patient died of pulmonary metastases six months after the first curettement.

Sclerosing sarcoma is radioresistant. Permanent cures are obtained in approximately one fourth of the cases in which prompt resection or amputation is performed.

The periosteal sarcomas of bone, including chondrosarcoma and sclerosing sarcoma, must be differentiated from osteomyelitis and myositis ossificans. In these rapidly growing neoplasms there may be pre-existing trauma, as in myositis ossificans, and a mild degree of fever and leukocytosis suggesting osteomyelitis. The most important diagnostic aid is the roentgenogram. Traumatic myositis ossificans usually forms a hard pal-

coma. A leukocyte count of over 15,000 favors osteomyelitis. Fluctuant areas probably contain pus and should be aspirated. Garre's non-suppurating osteomyelitis usually involves the shaft and extends half the length of the bone. In this benign condition, radiating spicules are rarely seen in the roentgenogram. In tuberculosis the neighboring joint is usually involved, but this is an exceedingly rare complication in cases of sarcoma of bone.

Chondroblastic Sarcoma.—This type of tumor was first described as a separate variety of sarcoma of bone by the writer in

1930 It is a form of osteolytic sarcoma which is frequently confused with giant cell tumor and referred to in some instances as a malignant variant of giant cell tumor. At the present writing the permanent cures obtained by roentgen irradiation and by curettage in cases of chondroblastic sarcoma and the proliferation of giant cells seen histologically have led other authors to return this new growth under the classification of giant cell tumor. Codman refers to it as an epiphyseal cartilaginous giant cell tumor and doubts that it is malignant. Nevertheless in the roentgenogram this tumor usually simulates sarcoma and in the writer's series some of the patients who have been well studied and carefully followed have died with metastases. The outcome is not seen in cases of typical benign giant cell tumors. Chondroblastic sarcoma is the one form of osteogenic sarcoma about which important differences of opinion still exist.

There is general agreement however that this is a tumor of the epiphyseal line in which the cartilaginous elements of the growth disks are involved during puberty. The epiphyseal lines of the upper tibia, lower femur, upper humerus and lower radius are the common sites. In the x-ray picture there is seen bone destruction with or without an expanded bone shell surmounted by definite periosteal reaction (Fig. 299). The tumor grows rapidly and fluid may be observed in the neighboring joint. At exploration the growth is found to extend into the soft parts surmounted by a layer of periosteum or it is found within a shell of bone. The major portion of the neoplasm invades the cancellous substance. The tissue is vascular but may show gray or bluish areas of cartilage. The characteristic microscopic features are remnants of hyaline cartilage (with or without calcification) intermingled with characteristic giant cells. Large chondroblasts which have a vesicular nucleus and a fair amount of cytoplasm are present in the stroma. The controversy hinges on the interpretation of the cartilaginous elements. Do these cells represent normal growth of the epiphyseal cartilage which at puberty is secondarily invaded by giant cell tumor tissue or are they a true neoplastic proliferation? In the writer's series of about twenty-five cases there are three patients who are

still living and have not undergone amputation. One of these patients was treated by means of curettage, radium implantation, Coley's toxins and roentgen rays more than twenty years ago and is still alive. In a fairly recent case a biopsy was performed and then deep x-ray therapy was administered and the patient has remained well for approximately ten years. Another patient was curetted and was reported five years later to be living and well. Fourteen patients in the series are known to have died of this disease. At present roentgen irradiation followed by resection is advised for other than weight

Fig. 300—Photomicrograph of a chondroblastic sarcoma showing the remains of calcified cartilage and typical large chondroblasts. Elsewhere in the tumor were many small nucleated giant cells. This lesion was explored in 1930 and received thereafter deep x-ray therapy. The patient was reported well in 1934.

bearing bones. The writer would still advise amputation for such a lesion in the tibia or femur despite the fact that the case illustrated in figure 300 has been controlled by deep x-ray. The condition can be suspected but not adequately diagnosed without a biopsy.

Osteolytic Sarcoma—Osteolytic sarcoma is a destructive tumor which arises in the marrow cavity near the end or in the mid-shaft region of a long bone. The age distribution of these patients is variable. The majority are young adults but some are of advanced age. The lesion shows an unusual

tendency to undergo pathologic fracture. In the roentgenogram a rapidly extending area of bone destruction is seen which dissolves the cortex without expansion and involves the periosteum and overlying soft parts (Fig. 301). The tumor appears grossly to be ex-

Fig 301.—Roentgenogram of osteolytic sarcoma showing an asymmetrical area of bone erosion and periosteal reaction overlying the tumor

tremely vascular and hemorrhagic, and its tendency to bleed excessively at exploration led to the caption by early authors of "malignant bone aneurysm." The disease is characterized microscopically by large malignant spindle cells and osteoblasts with numerous mitotic figures. There is little tendency to ossify, and in all probability the tumor represents a more malignant grade of osteogenic sarcoma, similar to or identical in its origin with that of sclerosing osteogenic sarcoma. Numerous giant cells may be present in the lesion, making it difficult to distinguish it at biopsy from a giant cell tumor. In elderly adults amputation affords the best chance of cure. In young adults roentgen irradiation will control the lesion sometimes for several years but will not cure the disease. On the other hand, cures by radical operation are obtained in less than 5 per cent, so that the more conservative treatment may be preferred to the loss of the limb in younger patients.

It is well to emphasize the fact that no didactic statements can be made in regard to the mode of therapy to be adopted in young persons for either chondroblastic or osteolytic sarcomas of bone. The treatment of choice will ultimately rest on the degree of success which is achieved by the newer methods of deep x-ray therapy.

Metastatic Carcinoma.—A large group of bone tumors are metastatic in origin. The most frequent cancers which give rise to such lesions are those of the prostate, breast, kidney, thyroid and lung. Metastatic cancers of the breast or prostate, which far outnumber the other forms in this group, usually produce multiple involvement of the pelvis, spine and skull. Mammary cancer with secondary deposits in the bone shows in the x-ray picture multiple foci of mottling due to a combination of bone formation and bone destruction (Fig. 302). With metastases from carcinoma of the prostate, there is a similar skeletal distribution of the lesions, but in this condition bone formation predominates with obliteration of the normal

Fig 302.—Roentgenogram showing areas of increased bone density and rarefaction produced by metastatic carcinoma of the skull. The entire skeleton, with the exception of the hands and feet, legs and forearms was similarly affected

bone markings. Carcinomas of the prostate and breast with bone involvement are best treated by means of deep x-ray therapy, which relieves pain and prolongs life. The improvement of symptoms observed with this form of treatment aids in establishing

the diagnosis. The daily oral administration of from 10 to 15 Gm of calcium gluconate over a long period of time may be extremely helpful. Pain may be diminished and calcification may take place.

The forms of metastatic carcinoma just discussed must be distinguished from Paget's osteitis deformans which is characterized by enlargement of the skull and increased density of the bones of the spine and pelvis. The skull has a characteristic "rigger wool" appearance and there is bowing of the tibiae with a wavy deformity in the cortical area sometimes accompanied by cyst formation but the striations of the bone are usually preserved. Metastatic carcinoma obliterates these striae; it usually does not metastasize below the knees and does not give rise to the characteristic bowing of the tibiae. In Paget's osteitis the blood level of alkaline

this is seen in the roentgenogram where the shadow in the soft part exceeds that in the bone. Osteons destruction proceeds from without inwardly and there is often no evidence of periosteal reaction. The microscope reveals a fascial sarcoma or a fibrosarcoma with numerous spindle cells and various amounts of collagen. The lesions are not radiosensitive and are often of a very low degree of malignancy. They tend to recur after local removal but five year cures have been established by ultimate amputation after two or three such recurrences.

Another form of tumor formerly classed as a periosteal fibrosarcoma invades the bone from without in a manner similar to that in case of fascial sarcoma. This is sarcoma of the nerve sheath and usually arises from the deep peripheral nerves. The writer knows of no case of sarcoma of the nerve

FIVE YEAR SURVIVALS IN MALIGNANT PRIMARY TUMORS OF BONE

No. of Cases	Form of Malignant Tumor	Five Year Survivals	
		No. of Cases	Percentage
138	Sclerosing osteogenic sarcoma	90	13
191	Osteolytic osteogenic sarcoma	11	0
239	Chondrosarcoma (primary and secondary)	33	16
26	Chondroblastoma	6	23
115	Epithelioid sarcoma	13	11
44	Fibrosarcoma	17	39
40	Multiplex leiomyoma	1	0
253	All forms of primary malignant tumors	106	14

phosphatase is usually markedly elevated. In metastatic carcinoma from the prostate the acid phosphatase level is elevated.

A solitary focus of destruction in a single bone is often produced by metastatic tumors of the kidney. The lesion in such cases is usually in a long bone (upper humerus or upper femur) at the site of nutrient vessels. Bone is destroyed without evidence of regeneration. Cancer of the thyroid, stomach and lung, metastatic melanoma and malignant lesions of the bladder may give rise to similar metastases.

Fascial and Neurogenic Sarcoma Invading Bone—So-called periosteal or prosteal fibrosarcoma is defined by the Bone Registry of the American College of Surgeons as a fibrous tumor arising in the outermost layer of the periosteum. These sarcomas however more often arise in the soft parts and invade the bone by direct extension. Evidence of

sheath with invasion of bone in which the patient has survived the five year period regardless of the form of treatment. Thus while the term spindle cell sarcoma may be used to refer loosely to the most frequent forms of sarcoma which invade the bone from without it is important clinically to distinguish the fascial from the neurogenic type.

Disturbances of the vessel and nerves and diffuse lipomatosis in a single extremity may also produce general rarefaction and deformity of the bone.

In rare instances other forms of sarcoma overlying the bone may show evidence in the roentgenogram of a large osseous defect. Wilms' embryoma of the kidney in children, malignant sacrococcygeal neoplasm, liposarcoma and myosarcoma all may produce such secondary bone lesions. In these malignant conditions while the prognosis depends

on the primary lesion, involvement of the bone is a serious complication and makes the outlook following any form of treatment highly unfavorable.

Early recognition and prompt radical therapy have increased the five year survivals among patients with malignant tumors of the bone. Among patients with sarcoma, those surviving the five year period are usually permanently cured, but this is not true of those with metastatic carcinoma or multiple myeloma. The accompanying table indicates that approximately 14 per cent of the patients with malignant tumors of the bone survive the five year period.

XVII. FRACTURES

GENERAL DISCUSSION

A fracture is the breaking of a bone or cartilage usually as a result of external violence

Varieties—A *simple fracture* is one in which there is no communication between the bone at the site of fracture and the outside air. Usually this means that there is no overlying wound of skin or mucous membrane. A *compound fracture* is one in which there is a communication between the site of fracture and the outside air through an opening in the skin or mucous membrane. This may have been caused either from within or from without. It is possible for an overlying wound not to communicate with the fracture, this then being a simple fracture although it is preferable for purposes of treatment to consider it compound. If an open operation is performed on a simple fracture or compound fracture is produced. If the unbroken skin and soft parts slough away in a simple fracture a compound fracture may be produced.

Fractures may be incomplete or complete. An *incomplete fracture* is one in which the continuity of the bone is only partially divided. There are several varieties. A *fissure fracture* is one in which there is a crack partially through the bone. This may be either transverse or longitudinal. A *depressed fracture* may involve only the outer table of the skull not passing completely through the bone. A bullet wound may create a *puncture fracture* without a break across the bone. A *greenstick fracture* is one which has occurred from marked bending so that the bone is splintered on the convex side but remains intact on the concave side like a splintered branch of a green tree.

A *complete fracture* is one in which the entire continuity of the bone is divided. The fracture line is single may be transverse, oblique, spiral or even longitudinal and often there is more than one line of fracture. A *comminuted fracture* is one in which there are two or more lines of fracture which divide the bone into more than two fragments.

At a joint this may be a combination of a transverse and longitudinal fracture producing a T fracture or a combination of two oblique fractures producing a Y fracture. An *impacted fracture* is one in which with or without lateral displacement the firmer cortical bone is telescoped into the softer cancellous bone. This occurs particularly at the neck of the humerus and of the femur. A *compression fracture* is one in which two opposite surfaces of the bone are driven closer together than normal. This usually is noted in cancellous bone with considerable fine comminution often resulting in a definite diminution in the area of bone shown in the x-ray picture as in fractures of the vertebrae. A *sprain fracture* is a sprain in which a small fragment of one of the bones has been pulled off usually at the site of a ligamentous attachment. A *spontaneous fracture* is one which occurs without apparent competent exciting cause. Strictly it is not spontaneous as the break is necessarily caused by trauma even though this is slight. It is usually found in patients with bone atrophy, osteogenesis imperfecta or general conditions affecting bone. A *pathologic fracture* is one which occurs without apparent competent exciting cause at the site of local disease of the bone.

Displacements of the fragments may be lateral, angular, longitudinal and rotary or a combination of these types. The displacements interfere with the proper axis of an extremity. A posterior angulation produces what is known as *dishing*. A longitudinal displacement may produce shortening of an extremity called *over riding* or it may result in separation of the fragments as seen in fractures of the patella or olecranon or in *overpull* in the use of traction.

A fracture is described as being located either in the shaft or in the extremities. At the ends of the bones there is a further designation according to the anatomical part broken e.g. surgical neck, tuberosity, condyle, head or articular fracture or epiphyseal separation. An articular fracture is one

in which the fracture line runs across the attachment of the joint capsule. An intra-articular fracture lies entirely within the joint. An epiphyseal separation is a fracture which passes wholly or in part through the epiphyseal line. It is often unrecognized and is of great importance because bony union of the epiphysis may result with arrest of growth. A subperiosteal fracture is a complete fracture without displacement in which it is believed that the periosteum has not been torn. Multiple fractures may be at different levels in the same bone or in different bones. The term *complicated fracture* is sometimes used when recovery will be complicated because of damage to artery, nerve or joint.

Etiology—*The Predisposing or Indirect Causes*—Age.—Fractures particularly of the clavicle, elbow and forearm are common between the ages of two and four years on account of unsteady gait and frequent falls. Between the ages of four and six years many greenstick fractures occur as the bones are soft. Between six and twelve if a fracture occurs near a joint there is liable to be epiphyseal separation. The incidence of fractures increases from six years on reaching its maximum between the ages of thirty and forty, that is it coincides with the age of greatest activity. On account of bone atrophy fractures of the neck of the humerus and of the neck of the femur are particularly common in old age.

Sex—The incidence is about the same in boys and girls up to four or five years of age, after which fractures occur more commonly in males up to forty-five. This is undoubtedly a result of their more active life and more hazardous trades. Some authorities state that fractures are from seven to ten times more frequent among males than among females during this period. After forty-five the number is nearly equal in the sexes with a slight preponderance among females in advanced age.

Bone atrophy is a predisposing cause of fracture as noted in old age from prolonged lack of use as in cases of paralysis or ankylosed joints and in general paresis, tabes and syringomyelia. Osteogenesis imperfecta or idiopathic fragilitas ossium is an inherited tendency to spontaneous fracture. Generalized bone conditions such as rickets and

osteomalacia and localized bone disease such as sarcoma, metastatic carcinoma, destruction of bone in acute osteomyelitis and bone cysts are favorable to the occurrence of fracture.

Exciting or Direct Causes—There are three exciting causes—direct violence, indirect violence and muscular action.

A fracture by *direct violence* is one in which the bone is broken immediately below the point of impact. Injury to the soft parts always accompanies the fracture which is frequently compound. The line of fracture usually is transverse or slightly oblique and is often comminuted. The common example at the present day is in a patient who has been run over by the wheel of an automobile.

A fracture by *indirect violence* is one in which compression or bending is exerted at a distance so that a bone gives way at its weakest point. A typical example of the compression action of indirect violence is seen in a fall from a height in which the person lands on his heels. According to the position of the skeleton in landing he may sustain comminuted fracture of the os calcis, fracture of the lower extremity of the tibia often with fissures running longitudinally, fracture of the shaft of both bones of the leg, compression fracture of one or more vertebrae or fracture of the base of the skull. Similarly in a fall on the extended palm may result in a fracture of the lower extremity of the radius, the head of the radius, the lower extremity of the humerus, the surgical neck of the humerus or the clavicle. The site of the fracture varies both with the exact position of the skeleton at the moment of impact and with the age of the patient. The bending action of indirect violence is well seen in fractures sustained in turning the ankle in which the weak point of the fibula immediately proximal to the external malleolus is the frequent site of fracture. If at the same time that the bending action occurs there is a certain amount of rotation of the body on the foot the fracture is often spiral rather than simply oblique. Fractures caused by indirect violence are somewhat less likely to be comminuted. If compound they are usually compounded from the inside by a fragment of bone which pierces the skin. The injuries of the soft parts are

those caused by the sharp ends of the fractured bone. Fractures by indirect violence occur much more commonly than those by direct violence.

Fractures by muscular action are less common, the most frequent examples being fractures of the olecranon and patella. A sudden contraction of the triceps or the quadriceps usually because of an unexpected movement fractures these bones transversely. More rarely a long bone is fractured by muscular action, e. g. the shaft of the humerus when the person is thrown, a baseball or the shaft of the femur when a patient with talipes merely rolls over in bed. The mechanism of fracture may be due in an individual patient to a combination of any two or all three of the direct causes.

The comparative frequency of fractures in various bones is difficult to determine. Many series of such statistics have been published including thousands of cases but they are usually in entire disagreement as to the order of frequency. This is easy to understand. The usual site of the fractures seen in hospital wards is different from that seen in the dispensaries, a hospital in a residential district sees fractures that are usually in other locations than those seen in an industrial or congested district, a hospital with an ambulance service may see more lower extremity and skull fractures while a hospital without an ambulance may see more upper extremity fractures because the patients are ambulators. All of the factors obviously account for the statistical variations.

There are probably more fractures of the upper than of the lower extremity. Fractures of the phalanges and ribs are probably most numerous. Following these without attempting to place them in order of frequency, the common fractures are of the lower extremity, of the radius, the region of the ankle, the metacarpals, the shafts of the bones of the leg, the skull, the clavicle and the humerus.

First Aid and Transportation.—Except on hospital ambulances, first aid after fractures is more likely to be rendered by laymen than physicians. In many instances this is the critical part of the whole treatment. It is necessary to know the principles of first aid for use while serving as ambulance surgeon but it is of even greater importance

to be able to guide and instruct the general public. Splinting where they lie is properly the first principle in fracture treatment but if it is lived up to it is obvious that the splinting will rarely be done by a physician. Splinting must be considered as only a means of aiding transportation, not a part of the definite treatment of the fracture. The physician must be prepared to instruct the public on the most effective manner of transporting a patient with a fracture to the physician's office or to a hospital. In general, those trained by the Red Cross, Boy Scouts, etc., know more about first aid than most physicians because little responsibility has been accepted by the physician until the injured person arrives at the office or hospital.

To quote from *An Outline of the Treatment of Fractures* issued by the American College of Surgeons:

The injuries resulting from fractures are not limited to those occurring at the time of the accident. Unsuccessful attempts to use the injured extremity may cause or increase displacement of fragments, increase the lacerations of soft parts and perhaps lead to penetration of the skin by the ends of the bone. Splinting of a limb is often a duty due to the lack of efforts of the bystander. A man is struck by an automobile, thus breaking his leg. Except for the broken bone without displacement the original injury may be merely a slight peroneal tear and a mild contusion of the soft parts, but he is helped to his feet and the leg gives way and the fragments slowly each other till a snapping off the posterior half of the bone makes the fall to the ground only to be picked up and carried to the sickle with the leg hanging. Larger blood vessels are torn and the end of the bone comes through the flesh, perhaps the skin and even the tibia. He is lifted with a coat he catches and is surrounded by people anxious to help. Someone sees that his leg is crooked and straightens it out. The exposed end of the bone re-enters the wound. He is lifted in a trouser and the dirt of the street. He is lifted and carried to a car or ambulance. The time someone carries the injured leg. He better intentions than coordination and the ends of the bone are cleaned and are not the bed of lacerated tissues and the contamination organs are well exposed all throughout the area. Dr. G. L. S. ride and in the transfer to the accident ward or the doctor's office unless he has been carefully splinted there, a more jolting and more damage. We think that his troubles were over. It is often the easiest to contain. Lack of efficient protection as he is lifted to and from the x-ray table and as he is by the ambulance, it is his still more injury.

Compare the exaggerated picture of a similarly injured man who is allowed to remain where he is until a proper splint can be applied or at least until he can have someone pull him on his foot as he is being lifted.

and carried whose examination is thoroughly but gently carried out and whose treatment is instituted with but little additional injury. The difference in these two cases as regards period of disability and amount of permanent functional disturbance is great.

Principles of first aid (1) If suspicious that a fracture is present render care as for a fracture (2) combat any existing shock (3) avoid every unnecessary manipulation (4) protect any existing wound by the best means available (5) splint effectively before transporting the patient wherever found and (6) transport carefully.

The injured person should first be examined rapidly in order to attempt to determine whether he is seriously hurt. The clothing usually does not need to be removed. In examining a patient try to keep all parts thoroughly covered except the part which is actually being examined at the moment. One should depend on pain, loss of function or deformity for the emergency diagnosis of fracture and should rarely if ever try to obtain crepitus or false point of motion. If the patient thinks that he felt a bone snap for emergency purposes one should be satisfied with his history and not attempt to prove the diagnosis on the street. If suspicious that a fracture is present always treat the patient as if the diagnosis of fracture had been confirmed.

The saving of life comes first and the saving of limb second. If the patient is in shock this demands treatment before anything is done for the fracture. There is no use in *splinting a limb carefully while neglecting to treat shock* from which the patient may be dying. On the other hand traction on an extremity may be the most effective means of combating shock. If morphine is available this is the first and best treatment for shock. It allays pain and thereby quiets the patient's restlessness. The body heat must be maintained by sufficient extra covering.

If a wound is present which possibly connects with a fracture it should not be washed out. A sterile compress should be placed over the wound preferably without the previous application of any antiseptic. Bleeding should be stopped. It is rare that this cannot be done with a firm compression bandage. Tourniquets should not be used until compression has proved of no avail.

Deaths have been caused by an improperly applied tourniquet which allowed some arterial blood to enter the part and only shut off the venous return. It is common to see all bleeding stop as soon as a tourniquet is removed. If a tourniquet must be used it should be loosened every half hour to allow blood to return to the part distal to the tourniquet.

Do not attempt to replace the fragments in a compound fracture with projecting bone. If the bone disappears beneath the skin in the course of the application of traction this should not cause anxiety. The patient must be operated on in any case to clean up the wound. It is important that word shall accompany the patient that the bone has been exposed in order to guide the treatment by the next physician.

If materials are not available to splint the fracture properly the patient should not be lifted into the first automobile and rushed to a doctor's office or hospital. It is far better to cover the patient adequately and let him lie on the ground where he was found until he can be splinted and moved in an ambulance. If it is necessary to change his position at all before splinting in the instance of an extremity fracture pull should be exerted on the injured part while he is being moved.

Special Indications in Individual Fractures—**SKULL**.—Keep the patient in the recumbent position; a pillow may be placed under his head. It is better not to use morphine; *the cerebral centers may be already depressed by the injury* and this depression should not be added to by the use of morphine. If for any reason it is believed that morphine is necessary it should be accompanied by caffeine. Any patient with a history of even momentary unconsciousness should be confined to bed and kept under observation. The symptoms of serious injury may not appear until a number of hours after the accident. In general the skull injury is of little importance but the possibility of laceration of the brain demands attention.

LOWER JAW.—Try to bring the lower teeth against the upper teeth gently. Apply the center of a narrow bandage under the chin. Pass one end over the top of the head and cross the two ends above one ear tying them

tightly at the base of the skull the crossing being on the side injured. Do not use a four tailed bandage.

CLAVICLE AND SCAPULA—Use a sling to support the upper extremity with the elbow flexed and a body bandage to diminish movement at the shoulder.

SPINE—If the mechanism of injury is such that a fracture of the spine may have been produced transport the patient as though a fracture had occurred even though no objective signs are discovered in a cursory examination. Death or permanent disability results more commonly from improper transportation of the patient with a fracture of the spine sometimes unrecognized than from any other injury. If the injured person complains of pain in his back it may be broken. If he complains of pain in his neck he may have a broken neck. Do not lift an injured person or his head until he has told you whether he can move his legs or fingers. If he cannot move his legs his back is broken. If he cannot move his fingers his neck may be broken. In either instance the spinal cord is injured. If the patient's body is bent while he is being carried in the former instance or if his head is lifted so as to give him a drink in the latter instance the injured spinal cord is inevitably ground between parts of the broken spine thereby destroying any useful remnant of the cord which may have escaped injury. Do not allow the injured person to sit up. If a fracture of the spine may be present and the victim is unconscious handle him as though his neck were broken.

For the patient with possible fracture of the dorsal or of the lumbar region the underlying principle of hyperextension should be observed in any moving and in transferring him from the site of accident. He should be carried face downward on a rigid support. Wherever found the patient should be slowly and evenly rolled over so that he rests on his abdomen on this rigid support. One of his forearms should be placed under his head which is turned to the side as in the Schäfer presentation method. Whenever the patient must be moved at all before the rigid support is obtained he may be rolled onto his abdomen on a sheet or blanket. This sheet may then be lifted by two per-

sons one at each end and the patient carried prone in this improvised hammock.

In case of possible fracture of the cervical vertebrae gently slide the patient sidewise onto a rigid support so that he rests face upward with the arms at the side. Never tilt the head forward. No pillow should be placed under the head or neck. Pillows or sand bags may be placed each side of the head to prevent rotation.

THIGHS—The injured person should be transported on a rigid support lying on the back. If the injury seems severe the thighs as well as the legs should be tied together. The position of the thighs and legs should be that naturally assumed. If enough assistance and the necessary material are at hand a body swathe may be placed about the pelvic girdle. This should be applied snugly but not tightly.

Traction—The only effective and advisable method for transporting a patient with a fracture of the long bones of either upper or lower extremity is by some form of fixed traction. This requires the use of a splint of the Thomas type. By fixed traction is meant that pull is exerted from fixed points above and below so that the traction remains the same whatever the position of the limb or splint. Over riding is characteristic of these fractures and there can be no generally effective immobilization without traction. In addition traction relieves pain and shock and prevents further damage during transportation. The fixed traction splint should be applied if there is any possibility of fracture between the hip joint and the foot or between the shoulder joint and the middle of the forearm no matter whether the injuries are simple or compound.

The full ring Thomas splint can be used on either upper or lower extremity. More generally applicable and advisable splints of the Thomas type are the Murray-Jones hinged arm splint for the upper extremity and the Keller-Blake hinged half ring splint for the lower extremity. These splints should be applied wherever the patient is found without changing his position.

General Requirements of Application—There are certain standards that are necessary in the application of this general method. It does not make any difference what particular procedure is used so long as

one appreciates what must be accomplished. In the use of traction there are six requirements: 1. There must be some adequate form of hitch, and it is necessary to protect the part beneath the hitch so that it will not be injured. 2. The traction hitch should be applied above the ankle or the wrist. 3. There must be some means of increasing traction by twisting so that the desired pull is obtained. 4. The extremity being in traction must be supported. One must not depend merely on traction for the entire support of the limb. 5. Not only must the extremity be supported from below, but lateral movement must be prevented. 6. In a case of

traction is being made, the whole limb is slowly lifted several inches from the ground. The half ring splint is slipped from the outer side beneath the extremity. The side bars of the splint are placed in the median horizontal plane of the thigh so that the ring rests against the tuber ischi. The strap is buckled over the anterior surface of the thigh. The lower end of the splint rests against the body of the assistant who is still applying traction. The ankle region is protected by cotton wadding or the shoe. A traction hitch is applied (an army traction strap or muslin bandage about the ankle or adhesive plaster to the leg). The traction hitch is fastened

Fig. 303—Lower extremity in a Keller Blake long half ring splint with fixed traction applied according to the Beelman Hospital method.

fracture of a lower extremity the whole splint must be suspended so that the heel will not at any moment rest on the ground, the floor of the ambulance or elsewhere.

EXAMPLE OF TYPICAL APPLICATION.—Take for example a case of possible fracture of the shaft of the femur (Fig. 303). The patient is covered with blankets. Morphine is administered if available under medical supervision. The foot, with or without the shoe on, is grasped firmly by an assistant with both hands placed laterally. Gentle steady firm traction is made in the axis of the extremity. Manual traction is maintained until splint traction is established. While

to the end of the splint and traction is increased by a Spanish windlass action with a tongue depressor and adhesive plaster or a long nail. The manual traction is then released. The extremity is supported in the splint by means of muslin hammocks and clips applied before the splint is put on or by a wide cotton bandage wrapped from below upward about the extremity and traction bars after traction is applied. Lateral movement is prevented by turns of muslin bandage tied above and below the knee in the former instance. The end of the splint is suspended to the stretcher bar or to the roof of the ambulance. A foot piece is advisable

if transportation is to be prolonged. The method of applying traction to the arm is quite similar (Fig. 304).

In hospital practice a traction splint should be applied immediately in the emergency room, if it has not been done before. The patient is transported to the x-ray room and to the ward with traction on. The removal of the patient's clothes is supervised so that if traction must be loosened, it is maintained manually until it can be reapplied. The traction splint is kept on until the patient is in the operating room and under an anesthetic.

were applied from the axilla to beyond the foot for fractures of the hip and thigh, but these are difficult to apply and probably do more harm than good. It is preferable simply to bind the thighs and legs together using the uninjured leg as a splint. [The editor considers that the long, side ("Liston") splint is preferable.]

For a fracture of the patella, leg or ankle a pillow which is drawn firmly around the part in its proper relation is fairly satisfactory. A padded posterior wooden splint will suffice for patellar fractures and two lateral wooden splints extending from mid-thigh to

Fig 304—Upper extremity in Murray-Jones binged arm splint with traction fixation applied according to the Beckman Hospital method

If a Thomas splint is not available, the first aid treatment of a fracture of the humerus should consist of binding the arm to the side of the body, with or without a pad in the axilla and with or without a padded wooden splint on the outer aspect of the arm, the wrist being supported by a narrow sling passed about the neck.

For fractures of the elbow, forearm, wrist or hand, padded splints of wood or heavy cardboard will suffice for transportation.

If a Thomas splint is not available for a fracture of the lower extremity, it must be appreciated that unless manual traction is exerted during transportation there is always danger of increasing the extent of the injury. Formerly, long, side wooden splints

foot may be used for leg and ankle fractures. For all fractures of the foot, any splint of firm material which keeps the heel and toes from touching any object will suffice.

It is important to remember that the type of first aid and transportation is a large factor in the ultimate recovery. It has been stated that in World War I the mortality of gunshot wounds of the femur was reduced from 80 to 20 per cent by the routine use of the Thomas splint. Physicians need to be cooperative in urging the public to carry out these methods of transportation and not insisting, as do some, that a fracture should not be touched until the patient reaches the doctor's office or the hospital.

Anesthesia.—Whenever any change in

position or manipulation of fragments is indicated an anesthetic should be used this assures relaxation of muscles and allows the surgeon to be free to do whatever he finds necessary. Because one believes that a reduction will be easy this does not justify failure to use an anesthetic. Even if it is possible to obtain a perfect reduction without its aid more damage to soft parts is liable to occur as a result of the resistance of unrelaxed muscles. The patient's statement that he can stand the pain is not of importance as the anesthetic is not given for this reason but to relax the muscles and allow a perfect replacement of fragments as possible.

Local anesthesia is the best in the form of an injection of novocain directly into the hematoma around the ends of the fractured bones. From 10 to 30 cc of a 1 per cent solution is sufficient. The site of the needle puncture is prepared by the application of tincture of iodine. The needle is inserted at a point close to the fracture site the plunger is withdrawn slightly until blood appears in the syringe the novocain is then injected. Relaxation is usually obtained within from two to five minutes. Unless the injection is into the hematoma as proved by blood in the syringe it is rarely successful. It is a simple procedure no extra anesthesiologist is required there is no struggle and consequently no danger of further displacement of the fragments either while the anesthesia is being induced or during recovery. Furthermore the patient can cooperate in the application of splints for example by sitting up for the application of a shoulder splint. Twenty-four hours after a fracture is sustained the blood is frequently coagulated diffusion of the anesthetic does not occur and no relaxation results. During the first twenty-four hours the anesthetic is quite uniformly successful. The only other contraindication is the occasional damage to a large vessel or nerve by the needle. Its use is indicated in all simple fractures of an extremity. If more than one bone is broken injection will be required at each fracture site. The relaxation usually lasts from one half to three quarters of an hour and gives sufficient time for the physician to reduce the fracture apply splints take a roentgenogram and if the position is not absolutely

satisfactory attempt reduction again without further injection of the anesthetic. Meantime the patient is awake and cooperative. Local anesthesia can rarely be used in children.

Two other forms of local anesthesia are used nerve block and regional anesthesia. Nerve block or plexus block requires considerable skill and practice. Brachial plexus block is excellent in cases of fracture of the humerus. Regional anesthesia does not demand special skill but does require a considerable amount of anesthetic. Both of these forms may be used in compound fractures. Regional anesthesia is excellent in fractures of the skull.

General anesthesia has been used in cases of fracture for a great many years. Ether is preferred for a long procedure. Nitrous oxide cyclopropane or ethylene with oxygen is suitable for short procedures. Ether gives more complete relaxation. All require the presence of a skilled anesthetist. In the use of a fluoroscope in connection with reduction there is some danger of ignition of the ether vapor or of ethylene unless a spark proof unit is used. Gas-oxygen is less dangerous from this point of view but its administration is difficult in a dark room. Rectal avertin is a valuable basal anesthetic.

Spinal anesthesia is excellent in cases of fractures of the lower extremities. From 80 to 100 mg of novocain injected beneath the dura in the fourth lumbar interspace will usually give complete relaxation for an hour. Accidents are rare when this amount is used. The crystals are dissolved in about 2 cc of spinal fluid.

Intravenous anesthetics are used considerably particularly sodium pentothal. It is best given in small doses repeated if necessary with skilled observation of the patient. Complete relaxation is liable to be accompanied by dangerous respiratory depression.

In the late treatment of fractures an anesthetic is sometimes advised when it is necessary to manipulate joints and break up adhesions. This is a dangerous procedure and should never be resorted to until every other method of stretching has been tried.

PATHOLOGY AND REPAIR OF FRACTURES

The intelligent care of fractures demands as an essential prerequisite a general knowledge of the pathologic condition accompanying the injury, the factors involved in the process of repair and the correlation of these with the disturbed physiology which one hopes to restore to normal. Without such a knowledge a fracture bids fair to remain an x-ray picture throughout its course. Such a point of view can never lead to really adequate treatment. A detailed discussion of the minutiae of pathology and repair involving the theoretical conceptions of the specific mechanisms involved and of the biochemistry and minute cellular activities brought into play has no place in this brief presentation. These are largely matters of academic interest. Merely a broad concept of what is known to occur following a fracture and during the healing process will be presented here and an attempt will be made to point out the way in which the process is reflected in the signs, symptoms and disturbed physiology and what these sign posts indicate with regard to treatment. Everyone knows what ecchymosis is and that it is one of the cardinal signs of fracture. But not everyone realizes that its location, the time of its appearance and its extent may be valuable indications pointing to important pathologic occurrences and vital therapeutic needs for the best results.

The consensus today based on both clinical and experimental evidence supports the view that the repair process following fracture is a *local phenomenon*. The general state of the patient's health, his age (with the exception of infancy and childhood), the existence of acute or chronic general disease (lues, arteriosclerosis, nephritis, tuberculosis, arthritides, cardiac disease, etc.) and the existence of generalized metabolic disturbances (osteomalacia, rachitis, scurvy,

diabetes, etc.)—none of these has any proved effect on the rate or degree of healing of a fracture. Of the various endocrine functions there is not one which has been shown to have any appreciable effect on the actual primary healing process in the presence either of excessive or of diminished activity. It is true that individual researches may indicate to the worker some effect (the literature is full of such examples) but for each contribution of this type one may find from apparently just as reliable a source a contradictory conclusion. Despite suggestive reports from certain reliable authors of a correlation between the serum calcium and phosphorus values and their interrelationship with fracture healing, extensive checks have failed to support this point of view. More over a patient with a negative calcium balance and with marked generalized bone decalcification has after sustaining a fracture shown a normal or increased rate of fracture healing *later decalcifying the callus to the same degree as the rest of the skeleton*. On the basis then of clinical and experimental findings by and large, major attention should be devoted to the local problems involved in the pathology and healing of fractures.

Consider what actually happens. At the time of injury the bone is broken and coincidently there is a variable degree of damage to the surrounding soft parts by laceration or contusion. If the laceration extends through the skin allowing communication between the fracture and the outside air, the fracture assumes a special significance as a *compound fracture*. The significance of compounding will be considered later.

The blood free in the tissues and the dead tissue resulting from the injury constitute irritants. In fact even with a moderate pathologic condition the patient may show within a few hours a rise in temperature, an increase in the leucocyte count and a raised sedimentation rate. There is in effect an aseptic inflammation, the parts surrounding the fracture are rapidly infiltrated by hemorrhage, edema and inflammatory exudate. Here then is the first clinically applicable knowledge of pathology. At the time of injury and for a variable period of from ten to thirty or forty minutes after injury the part may be said to be in a state of local

shock. It is analgesic after the initial momentary sharp pain of the fracture and its neuromuscular apparatus is practically paralyzed. A patient seen in this period will state that the arm or leg is numb. It will be markedly flaccid and relaxed. It is in this stage that a bystander by merely pulling on the part can readily and accurately reduce a dislocation or even a badly displaced fracture with practically no pain to the patient. It happens practically every day on some field of sport or athletic activity and is accepted as a matter of course even by the layman. But only within the last few years has there been an appreciation of its application to the emergency use of traction through the application of the Thomas type of arm and leg splints with windlass traction which is now the approved standard of the American College of Surgeons as represented by its Fracture Committee (See section on First Aid Treatment of Fractures.) The use of immediate emergency traction on fractures if universally adopted will constitute the biggest single advance in the treatment of fractures in the present generation.

Following the passing of this short period sensation returns to the part and with pain comes muscle spasm and with muscle spasm there is the risk of increased deformity and additional interference with the blood vascular and lymphatic circulation. Within a few hours hemorrhagic and inflammatory infiltration has changed the shortened and spastic muscles from elastic extensible structures to hardaceous semisolid masses which can be stretched only with great difficulty even with damage. These muscles now constitute a mechanical bar to reduction. *Had the fracture been reduced and held before this happened the hardened and distended tissues would act instead as splinting for the reduced fracture.* This is the basis for the general principle that a fracture should be reduced as soon after injury as possible. Since this process is rapidly progressive and is complete within from six to eight hours it becomes obvious that one should think of reduction in terms of minutes after injury not in terms of hours or days. An hour spent in waiting around an accident ward may mean the difference between ease and difficulty of reduction.

This is of major importance in any fracture of the shaft of a long bone and of less practical significance in fractures such as Colles fracture at the wrist and uncomplicated malleolar fracture at the ankle where muscular resistance is not so potent a factor. It is however a matter of considerable import in cases which require skin or skeletal traction. When a patient has waited overnight to have pin or wire or adhesive traction applied what might have been an easily accomplished reduction by the stretching of elastic and extensible muscle bellies with a minimum of trauma may turn out to be an indifferent reduction accomplished with difficulty through the necessity of dealing with infiltrated and relatively inextensible elastic muscle masses. The blame for failure is placed on the shortcomings of traction and suspension instead of on ignorance of or lack of consideration for the pathologic change going on during the overnight wait. If emergency fixed traction had been applied in the interim much of the difficulty would have been obviated. When a wait is necessary this type of traction is the best means of minimizing the potential damage due to delay.

Following this pathologic change there is clotting i. e. laying down of a fibrin network in the hemorrhage and exudate in the tissues. This network joins the bone ends and adjacent soft parts in a web of interlacing fibrils along which tissue repair is to take place. The remaining fluid portions of blood and exudate seep to the surface slowly along the tissue planes if the soft parts about the fracture are but little lacerated or appear rapidly beneath the surface if there has been extensive laceration of the soft parts. The ensuing discoloration of skin due to the presence of the blood pigment in the fluid portion of the blood is known as ecchymosis. It is obvious that an early rapid appearance of ecchymosis at the fracture site indicates a large amount of tissue damage proportionately greater the deeper the involved bone lies from the skin. *Ipso facto* it indicates the need for methods of treatment which will allow maximum early attention to the pathologic condition of the soft parts. On the other hand ecchymosis which appears late particularly at a point distant from the fracture indicates a

minimal amount of soft part damage with a more favorable prognosis for the early return of function and a less urgent necessity for intensive early care of the soft parts. If the elbow joint is involved for example as in fractures of the radial head or lower humerus and in dislocations very early ecchymosis on the front of the elbow (some times within an hour from the time of injury) indicates extensive laceration of the joint capsule and brachial arteries and a threat of ossification about the front of the elbow. Special treatment is urgently needed under such circumstances.

As a result of the death of the hemorrhage and progressive circulatory stagnation (lymph and blood vascular) following rapidly after fracture the pH of the local tissue fluid becomes acid. With this acidity there occurs over the next week or ten days a decalcification of the fracture site. These are the facts whether or not they are correlated or merely coincident or not is at present in the field of speculation. The calcium so removed from the fracture site is held locally in the soft parts probably by an adsorption affinity for fibrin and collagen. The latter part of this statement is possibly speculation the first part is fact.

Coincident with this chemical change the healing process proceeds as with any other wound, by the growth of new fibroblastic cells along the fibrin network from all available connective tissue sources—marrow cavity with its so-called endosteum, periosteum and fascial planes and muscular stroma if they are opened into by the fracture.

This healing process is what one would expect in any wound and is explicable if at all, on the same basis as all wound healing. At some stage during the process calcium is deposited in the healing tissue to surround the cells and the tissue then is called *cellus* instead of granulation tissue. Whether or not osteoid tissue (early callus) contains calcium or merely a preosseous substance in which calcium is deposited (Leriche) whether or not specific bone forming cells are involved in the process either by direct growth and migration of osteoblasts from adjacent bone and periosteum and endosteum or by 'metaplasia' of connective tissue cells in reply to the physiologic de-

mand and whether or not ferment activity (phosphatase) is an integral part of the story and if so whence the ferment is derived are at present matters of academic interest. The practical clinical application of this phase of the story lies in the fact that the consensus is that the calcium deposited in the newly formed connective tissue is for the major part derived from local decalcification at the fracture site and that its deposition occurs coincidently with the alteration of the pH of the tissue fluids locally toward the alkaline side as a result of removal of tissue death products and correction of stagnation of tissue fluids by a restoration toward normal of the lymphatic and blood vascular circulatory efficiency of the part.

Moreover there is a great deal of evidence to support the viewpoint that this deposition of calcium into the healing tissue to form bone can occur only while the tissue is still undifferentiated. Once the healing tissue becomes adult formed fibrous connective tissue no bone formation occurs. If this is so and if our ideas on the deposition of calcium as a result of phosphatase activity within a limited pH range approaching the alkaline side are correct it would seem that if the acid pH phase is prolonged by reason of the amount of tissue death or by reason of a circulatory status which makes impossible the carrying away of the products of tissue death the healing tissue may differentiate before any calcium deposition can be effected with the result that the healing remains fibrous (the so-called non union) or the deposition of calcium in the lower pH ranges may be so slow that so-called delayed union occurs.

In this understanding of the process lie possible explanations for many of the apparent vagaries connected with fracture healing. It is to be kept in mind that once local destruction of intrinsic bone circulation has occurred as a result of fracture the most important factor in the maintenance of efficient nutritive and scavenger levels is the available accessory circulation of the soft parts—blood vascular and lymphatic which can operate at physiologic levels and substitute for the destroyed circulation to the bone. On this factor hinges to a large extent how much growth of healing granula

tioo tissue can occur and how soon deposition of calcium in this tissue can take place. The neck of the femur presents an excellent example of this phase of the problem.

As will be noted from the descriptive paragraph beneath figure 360 the amount of healing tissue produced is dependent on the supply of available *vascular soft parts* and the calcification of that living healing tissue to produce bone is dependent on the *vascular efficiency of the region* in reference to returning the reaction of tissue fluids toward normal by reason of correcting the local stagnation of tissue fluid and the removal of products of tissue death hemorrhage and exudation before the healing tissue becomes differentiated into adult fibrous connective tissue.

The study of these phenomena has led to an appreciation of the fact that attention to the circulatory efficiency of the part particularly in its more minute phases rather than in the major vessels is a big factor in promoting normal or rather average healing. This has a very definite bearing on the present day tendency toward pin fixation and operations as methods of choice in many cases when they can be combined with early active mobilization of the part early in intensive physical therapy and elevation since those three adjuvants in that order are the most effective means of improving the local circulatory status.

The pathologic condition of the fracture line is a matter of considerable importance in an evaluation of the suitability of various methods of treatment in a given case.

Some guides for fracture treatment based on the foregoing discussion of wound healing can be briefly set down as follows:

1 First aid in fracture cases should aim at as extensive and complete immobilization of the part as possible and should include fixed traction if possible applied as soon after injury as possible and with as little trauma as possible.

2 Shock and injury should be treated coincidently. *Except in moribund cases it is a mistake to treat shock until the patient is normal and then to treat the fracture.* The treatment of shock should be carried out while the fracture is being given early definitive treatment.

3 Reduction should be accomplished

before the muscles and soft parts have lost their elasticity by reason of infiltration by exudate and hemorrhage. This is just as true for traction suspension open reduction and fixation pin fixation or any other method as it is for manual manipulation and plaster fixation. It means that reduction by traction suspension should be complete within eight to twelve hours that open reduction should be performed within that time if possible and that pin fixation should be applied and should attain reduction with fixation by plaster or apparatus within that time.

4 If the patient is seen after the loss of elasticity in the tissues has occurred intensive effort should be made to get rid of the pathologic accumulations in the tissue and reduction by any means should be delayed until elasticity is restored unless some urgent necessity for it exists. Under proper use of splinting position physical therapy and muscle stimulation this delay should rarely be more than forty eight or seventy two hours and will often be less than twenty four hours.

5 That method of treatment which allows the most active function of the extremity during bone healing is if it can be adequately carried out the best method from the dual standpoint of successful bone healing and of short convalescence time. Whether or not the theoretically best method is practically applicable in the individual case depends upon the analysis of the patient and his lesion (bone and soft parts) upon the qualifications of the doctor and upon the organization and equipment available.

6 Physical therapy should be regarded as an adjunct to or an inadequate substitute for active function and both patient and doctor should thoroughly understand this.

7 Postreduction immobilization should aim at as rigid fixation of the fragments as possible coincident with as extensive mobilization of the extremity as is compatible with the method of treatment used.

8 No matter what the method used its general purpose should be metaphorically to 'wish the fragments into place with the immediate abolition of all pathology to hold them in position by moral coercion and to

let the patient immediately go about his regular business. How closely this ideal can be approached depends upon the method used but the approach should be in each instance as close as the limitations of the method will allow.

9 The necessity for after treatment and rehabilitation measures is in inverse proportion to the efficiency with which the principles of treatment have been carried out by the method used.

10 Fractures heal primarily by the formation of bone in the soft parts about the fracture site and the circulatory efficiency in these soft parts is a vital factor in the process.

11 In compound fractures the treatment of the wound and adequate reduction and fixation of the fracture should be coincidental and should be accomplished just as soon in terms of minutes after injury as possible. Early wound treatment with delayed reduction and fixation is a mistake.

The pathology of the displacement of fragments has a definite bearing on the methods of reduction and should together with the resisting forces constitute the basis of any intelligent effort at reduction.

Lastly, it is essential to recognize that for each region of the body there are important soft part structures liable to damage and that the examination of the patient includes elimination of the possibility of injury to them since the soft part lesion if present may constitute an urgent reason for altering from the beginning the method of treatment ordinarily used for the fracture in question. For instance in a lesion involving the middle third of the humerus the radial nerve is frequently injured. If this is not noted at the time of the original injury it may not be discovered until six or eight weeks later when immobilization is removed with resultant difficulties in the handling of the nerve injury. Similarly the median nerve at the wrist may be involved in badly displaced Colles fractures and in lunatic dislocations. The peroneal nerve is often involved in lesions about the fibular neck or by direct violence in this region though the fracture is of the tibia. Lesions about the internal humeral condyle may involve the ulnar nerve and those about the external condyle may involve radial or superficial radial

nerves. Dislocation of the shoulder or surgical neck fractures frequently involve the axillary nerve. Supracondylar fractures of the humerus with displacement are the commonest cause of Volkmann's ischemic contracture and the local tension about the front of the elbow and the state of the radial pulse before reduction after reduction and in the immobilized position must be carefully noted. One frequently sees cases in which prompt and adequate provision for the correction of the circulatory embarrassment has aborted a Volkmann's contracture the very early signs of which were already present when the patient was first seen. The author has seen many cases in which if the ordinary routine procedures had been followed without a careful check on the radial pulse throughout Volkmann's contractures would undoubtedly have been imminent. Unfortunately in many cases a check on the radial pulse is not considered as part of the examination and handling of a lesion of the elbow and there are disastrous results. It is only a knowledge of the peculiar pathology of supracondylar fractures which makes the name of the fracture itself immediate concern for the radial pulse.

There are numerous examples of impending disaster lurking in the lesions of the soft parts complicating fracture. Each region of the body has its soft part trap so to speak and it behooves the surgeon to know what it is so that it can always be looked for anticipated and if possible avoided.

DELAYED UNION AND NON UNION OF FRACTURES

On the basis of experimental procedures clinical observation and roentgen studies the present day conception of the problem of delayed union and non union may be epitomized in the following brief statements the clinical bearing of each statement being briefly summarized. The details of the supporting evidence are furnished in the articles listed in the bibliography.

I All fractures heal as do wounds elsewhere unless there is a mechanical chemical or anatomical bar to healing. This healing in common with that of wounds of the soft parts takes place through the medium of new connective tissue known as granulation

tissue. When referring to delayed union and non union one in reality refers to a delay or failure in the process of calcium deposition in the healing connective tissue which is commonly designated as new bone formation. The anatomical bar to healing lies in the absence of a sufficient accessory circulation to compensate for that destroyed by trauma and to remove adequately and rapidly the products of tissue death. Such regions of the body even under apparently optimum conditions are characterized by a slow average healing time and by the frequent occurrence of delayed union and non union in adults. The neck of the femur (subcapital or midcervical), the junction of the lower and middle thirds of the tibia, the scaphoid of the carpus (proximal half) and the base of the fifth metatarsal are characteristic regions.

In patients who have fractures in these regions and simultaneous fractures in regions not so characterized there is no perversion of healing in the latter, all other factors except location being equal.

II Variations in the character and amount of the healing process in bone following fracture are dependent on factors limited to the region of the body involved quite independent of the subject involved.

Slow union and non union in the adult are not dependent on the age (*per se*) of the patient on his general state of health on the presence of chronic general disease such as syphilis or cardiovascular or renal disease on general wasting due to other causes on general metabolic disturbances affecting either the general calcium and phosphorus metabolism (osteomalacia) or other phases of metabolism (diabetes) or on acute infectious disease. Non union except for mechanical reasons is practically never seen in children.

III The four factors involved in the mechanism of the healing of fractures and capable of being clinically influenced are (1) the local pathology (2) the growth of granulation tissue (3) an available local source of calcium for the ossification of the healing tissue and (4) a proper biochemical status of the local tissue fluids throughout the healing process.

1 Local Pathology.—The items of importance under this factor are (a) The

amount of tissue necrosis. When massive it destroys the available sources for the growth of granulation tissue and under all circumstances creates a pH to the acid side (often markedly so) in the hematoma and tissue fluids about the site of the fracture. This pH is of importance in the production of the local source of calcium and is the essential early stage of the biochemistry of the tissue fluid. Its persistence interferes with calcium deposition.

(b) The hematoma or blood effusion at and about the site of the fracture influences the growth of granulation tissue through its fibrin content and the possible persistence of its fluid content *in situ* and also through the establishment of a local source of calcium under proper conditions of pH in the tissue fluid by acting essentially as a decalcifying fluid and through adsorption affinity between calcium and its fibrin content holding the freed calcium *in situ*.

(c) The circulatory status of the part (including the lymphatic and tissue fluids) in the early and late stages of fracture healing. Its significance lies in its influence on the growth of granulation tissue and on the establishment and utilization of a local source of calcium through its influence on the pH of the tissue fluids.

(d) Chemical and physical influences through their effect on the growth of granulation tissue and the biochemical status of the part. Under the former may be noted the therapeutic use of chemicals locally (disinfectants, etc.) and infection and under the latter the use of such agencies as roentgen rays and diathermy and constant movement of the fragments.

(e) The mechanical element i.e. the interposition of living or dead material impermeable to the growth of granulation tissue between the fragments.

2 Growth of Granulation Tissue.—The items of importance under this factor are as follows. (1) All other factors being equal the amount of exudate produced is directly proportional to the amount of granulation tissue produced.

(b) The destruction of available sources for the growth of granulation tissue.

(c) The anatomical characteristics of the part regarding sources for the growth of granulation tissue and accessory circulation.

(d) The amount of fluid persisting for a long period at the site of the fracture

(e) Elements *d* and *e* mentioned under local pathology (chemical and physical influences and the mechanical element)

3 Available Local Source of Calcium.—The items of importance are the amount of bone necrosis the density and degree of fragmentation of the necrotic bone the influence of fibrin and collagen in fixing the calcium locally through chemical affinity and the biochemical status of the local tissue fluids

4 Proper Biochemical Status of the Local Tissue Fluids Throughout the Healing Process.—This factor involves the necessity in the local tissue fluid of a pH on the acid side in the early days following the fracture in connection with the establishment of a local source of available calcium and a reversion of the pH toward the alkaline side before the calcium made available can be to any extent deposited in the new tissue to form bone. The constituents normally involved in this phase of the process are the amount of tissue necrosis and the circulatory status (blood and lymph) of the part

What, then, can be done to prevent delayed union and non union? The objects of concern are as follows:

1 Early and accurate replacement of displaced fragments with assurance at the time of reduction that there is no interposition of tissue

2 The restoration to normal of the lymph and vascular circulation as rapidly as possible through elevation of the part early physiotherapy and the use of functional muscular activity whenever possible

3 The meticulous care of wounds in cases of compound fractures. Gentleness and conservation of sound tissue are not incompatible with thorough and efficient debridement. It pays to be conservative on the score of considering a debrided wound safe to sew up tightly. Chemical disinfection of a wound is not desirable. No method of wound treatment which creates tension in the tissues can be considered sound.

Where facilities for operative work on bone are of high standard as regards equipment technique and personnel many feel that in an open fracture rigid fixation of the frag-

ments by plate or screw at the time of the debridement with the wound left open is justified through minimizing the chances for delayed or non union by eliminating the foothold for infection engendered by constant movement of the fragments. Such a procedure is never justified unless the facilities for carrying it out are as specified.

4 Where the facilities for operative work on bone are of the highest standard as regards equipment technique and personnel it is today the belief of many that operative reduction with internal fixation sufficiently rigid to permit postoperative active mobilization in balanced suspension is the ideal method for fractures of the long bones in adults. It is certainly very doubtful whether operative reduction and internal fixation are justifiable except on the basis of absolute necessity unless rigid fixation can be secured since the early active use of the musculature as an aid in the minute circulation is one of the chief recommendations for the use of the method. Any necessity for postoperative immobilization nullifies this important advantage. Moreover it is felt that if open reduction is indicated it should be done within the first few hours after injury in order that the blood dead tissue and inflammatory exudate can escape through the operative wound or can be removed. This minimizes the burden placed on the local circulation in removing products of tissue death in order that the pH of the tissue fluids can revert toward normal as rapidly as possible thereby facilitating the early deposition of calcium in the undifferentiated healing tissue.

When the fracture lies in a region characterized by slow or indifferent healing the rigid internal fixation can be augmented by the use of osteoperiosteal or other forms of grafts as prophylaxis against non union.

It is to be strongly stressed that the use of operative reduction as a method of choice can be conservatively adopted only when exacting conditions as to organization equipment personnel and technique can be met and when the mechanical principles involved in securing rigid fixation capable of standing functional strain are thoroughly understood.

How should one treat non union? By creating the essential factors for new bone

formation at the site of fracture—death of tissue—adequate granulation tissue—a local source of calcium and an adequate circulatory status for the part—not for the bone alone

A bone graft, there are many reasons to believe does not grow but acts as a source of calcium for the calcification of the healing granulation tissue and as one of the sources for the enzymes concerned in the calcium deposition. The removal of fibrous tissue and of sclerotic bone aids circulatory augmentation and granulation tissue growth and invasion. The graft is rarely efficient enough fixation to allow of early active function, particularly since osteoperiosteal or clip grafts should be the most effective type and are so clinically and experimentally. If possible there should be added to the graft the rigid fixation obtainable from plate screw or other rigid means when feasible followed by early active function. The postoperative treatment should follow the lines laid down for the prevention of delayed and non union in a fresh fracture.

In addition to the prophylactic measures against delayed and non union referred to previously and the operative treatment of the condition after it has occurred the following measures are so more or less common use on the basis of the rationale cited in each instance

1 "Needling" of the fracture site consisting of passing repeatedly about and through the fracture site a sharp heavy needle. This produces a certain amount of tissue death and hemorrhage about and between the bone ends and sets up a variable degree of inflammatory reaction with concomitant circulatory change. According to one school of thought this may "stimulate" osteoblasts to produce bone. According to the other it recreates the original pathological conditions of the fracture and is followed by ossification in accordance with the rationale suggested under the discussion of fracture repair. At any rate this procedure is followed by union in a certain number of cases. There is no criterion whereby one may gauge which fractures are apt to respond to this treatment.

2 The injection of whole blood within and about the bone ends. The same discussion applies here as in the case of "needling" without injection.

In addition to whole blood various other milky containing substances have been used with similar results.

The use of calcium emulsions for injection has been attempted in the hope of augmenting the available local supply of calcium to be used in callus formation. In a fresh fracture such calcium is always available from the dead bone at the fracture site. In instances of late non union this is not the case and theoretically injection should supply a definite need. While success-

ful use has been reported of this procedure it does not seem on the whole to be any more valuable than plain needling or the injection of other substances.

3 The use of Bier's hyperemia intermittently over a considerable period of time. The effect here is on the circulatory status of the part and may work through the biochemical status of tissue fluids so created. At any rate its use is at times followed by union.

4 The tapping or gentle malleting of the bone at the fracture site (when it is subcutaneous) intermittently over a period of time. This accomplishes perhaps the same result as 1 and 2 without penetration of the skin. It is subject to the same interpretation as those procedures.

5 The initiation of weight bearing in cases of fracture of the lower extremity as by so-called "Roller walking irons," walking spurs and braces. Here again there are two views as to the mechanism of the healing sometimes induced, that it is a "response by osteoblasts to a physiologic demand" or that the inflammatory reaction induced by weight bearing in the presence of non union acts in accordance with the rationale of callus formation as suggested under the description of the repair process in fractures. Here again the procedure is sometimes successful and sometimes not with no known criteria whereby one can estimate the probabilities.

6 Boring numerous holes (after open exposure) in all directions through the fracture line from both fragments using a drill. This creates channels through sclerotic bone for revascularization of the fragments leaves in the channels and surrounding soft parts a certain amount of bone debris removed by the drill and sets up the original status of the pathological condition. It is subject to the same remarks as is the suggested mechanism of fracture healing under the discussion of that subject. It is perhaps the most successful of the methods described outside of grafting procedures and may be followed by walking plaster or brace weight bearing.

FRACTURES OF FACIAL BONES

Fractures of the facial region may be divided into four principal groups: (1) mandible (2) maxilla (3) zygomatic or malar bone and (4) nose. These may be sustained separately or together and may be complicated by injury to the overlying soft tissues.

Fractures of the Mandible.—The mandible is fractured more often than any other bone of the face usually by direct violence such as a blow of a fist, an automobile accident, a gunshot wound or a fall on the chin or during the extraction of a tooth. In some cases the fracture occurs at a point some distance from the place of impact.

Location of the Fractures.—The mandible is fractured in one place in about two thirds of the cases and in two or more places in one third. The commonest single seat of fracture is the angle closely followed by the mental foramen. Fractures of the symphysis and the neck of the condyle occur in 7 or 8 per cent of the cases while fracture of the coronoid process is very rare. In cases of double fracture a break in the region of the mental foramen on one side and a break at the angle on the opposite side are found most frequently.

Diagnosis.—Fracture should be suspected in every case of trauma to the region of the lower jaw until careful examination proves

otherwise. In many cases a patient is discharged from the accident ward of a hospital after receiving treatment for simple lacerations or contusions of the face only to return several days later with symptoms of an infected or unreduced fracture. With a history of trauma the most important points in diagnosis are as follows: inability of the patient to bring the lower teeth into correct occlusion with the upper teeth; severe pain at the site of fracture when the patient attempts to bite a hard object such as a wooden tongue blade inserted between the teeth; and preternatural mobility of the teeth on each side of the fracture. In a fracture through the region of the mental foramen the chin fragment is drawn down by the depressor muscles while the fragment posterior to the fracture is drawn up by the levators (temporal masseter internal pterygoid). In fracture through the ascending ramus or the neck of the condyle there is shortening from angle to condyle; hence the chin and lower incisor teeth deviate to the affected side. When the jaws are closed the upper and lower molar teeth meet sooner than those of the opposite side. It is rarely necessary to subject the patient to painful manipulation to elicit preternatural mobility or crepitus. Good x-ray plates of both sides of the jaw including both condyles should be made in all cases of suspected fracture of the mandible. The region of the symphysis is best studied roentgenographically by means of a 2¼ x 3 inch occlusal film. The x-ray plate is a valuable aid in determining the direction of the fracture, comminution, injuries to the roots of teeth and involvement of teeth in the fracture. It plays only a minor part in ascertaining the position of the fragments.

Treatment.—Practically every fracture which occurs in the part of the mandible occupied by teeth is compounded into the mouth and is exposed to infection. Early removal of tooth roots exposed in the line of fracture of badly diseased teeth wherever situated and of tartar deposits minimizes the danger of infection. Early immobilization of the fragments also reduces the tendency for infection from the mouth to work its way down in the fracture line. Throughout the course of treatment the patient should be encouraged to use a tooth brush and a

mouthwash containing hydrogen dioxide. The cooperation of the patient is essential in maintaining cleanliness of the mouth. No amount of cleansing by a second person will compensate for negligence on the part of the patient himself.

Fixation of the Fracture—In the mandible more than in any other region accurate realignment of the fragments is necessary, because the slightest deviation of the parts (except in edentulous patients) will result in malocclusion of the teeth and consequent interference with proper mastication. The fundamental principle therefore in treating these cases is fixation of the fragments so that the teeth of the lower jaw will be in proper relationship to those of the upper. Much space is given to surgical texts to obsolete methods which are not practicable for the surgeon who sees the average case. Re-

molars on both sides of upper and lower jaws, the upper first incisors and the lower four incisors, and joining these three pairs of approximating wires with three single wires passed through the eyelets and twisting the ends together after the teeth have been brought into proper occlusion. If the teeth usually employed for wiring are absent, diseased or otherwise unsuitable as attachments, then other teeth are used, the aim being to have three pairs of eyelet attachments. Occasionally where the teeth are not sufficient in number and stability for direct application of eyelet wires, a half round wire arch of plain heavy German silver is attached to the labial aspects of the teeth with wire ligatures. The teeth usually must be wired together for from four to six weeks to obtain union of the fracture. The patient must be kept on a liquid diet and fed

lance on a head bandage alone in the ordinary cases has no more value than would a mere bandage in a fracture of both bones of the forearm. Direct wiring or plating of the fragments should not be attempted in recent fractures which communicate with the mouth. In 90 per cent of cases of fracture of the mandible, no matter where situated, adequate fixation can be obtained by fastening the lower to the upper teeth by means of wire ligature according to the principle of Gilmer. The other remaining 10 per cent may require cooperation of the dental laboratory for the preparation of the more complicated interdental splints. With a little practice and attention to details, the surgeon can readily master the technique of application of the wires. Briefly, the method consists in fastening 6 mesh strands of 24 gauge brass wire with an eyelet made in the middle of each strand around the necks of the pre-

through a tube. There is usually no difficulty about this, the liquid passing easily through spaces between the teeth or back of the last molars. It is never necessary to extract a tooth to provide space for feeding. Infection sometimes occurs about the site of fracture requiring incision and drainage, removal of sequestrums, etc. There are certain complicated types of fracture of the mandible requiring more elaborate methods of fixation which are described in detail in various specialized textbooks. Skeletal fixation is occasionally used in cases in which teeth are not available.

Fracture of the Maxilla—Fractures of the maxilla are much less common than those of the mandible. They are often as o-

ments is usually due to the direction of the traumatizing force and sometimes to gravity.

Most fractures of the maxilla fall under the following heads (1) fracture of the alveolar process alone (2) unilateral fracture across the facial aspect above the roots of the teeth and through the hard palate and (3) bilateral horizontal fracture at

be fractured or teeth may be broken off. It is usually necessary to remove the detached fragment together with the teeth in it.

2 Unilateral fracture of the maxilla is usually caused by direct force coming from in front or from one side. There are symptoms of contusion of the side of the face and the entire maxillary dental arch on the

Fig. 307—The teeth are fastened in occlusion by means of twisting the ends of the connecting wires.*

one level above the hard palate sometimes accompanied by extensive comminution and crushing of the upper portion and complicated by fracture of the nasal maxilla and other bones.

1 Fracture of the alveolar process may occur in the extraction of teeth or may be due to a blunt localized force. In addition to the break in the bone tooth roots may

side of injury is usually depressed. By gentle manipulation mobility of the fragment can be demonstrated. Many cases can be successfully treated by pushing the fragment back in place until the teeth are in occlusion and then wiring the teeth of the sound side of the maxilla to those of the mandible.

* Ivy and Curtis: Fractures of the Jaws, Lea & Febiger, Philadelphia.

3. *Bilateral horizontal fracture* is usually caused by a direct blow from in front, such as occurs when a driver's face strikes the steering wheel of a suddenly arrested automobile. In the majority of cases the entire upper jaw is displaced backward and sags downward posteriorly so that the upper teeth are distal to the lower and only the last molars occlude, leaving a space between the incisors in front. The entire dental arch can be moved as a unit. The hard palate may be intact, or the case may be complicated by a longitudinal median fracture with either spreading or narrowing of the dental arch.

guided into position, and after a week or ten days, when occlusion of the upper and lower teeth has been regained, they can be fastened together with wire ligatures for a period of three or four weeks until union is complete. Fixation of upper jaw fractures can also be accomplished by means of traction wires from the upper teeth on each side piercing the cheeks and attached to bars on a plaster of paris headcap (Federspiel).

Fracture of the malar, or zygomatic, bone is always due to direct violence, and usually breaks occur at or near its junction with other bones, the body of the malar being depressed and often impacted (Fig 308).

Fig 308—Skull showing usual lines of fracture of malar bone *

Treatment.—Fixation by means of the mandibular teeth is not advisable at first because of the mobility of the lower jaw. Support should be obtained from the cranium by means of a head apparatus and a reversed Kingsley splint. The writer has had made an emergency apparatus of this type which can be kept on hand in two or three sizes so as to be immediately applicable. It consists of a heavy metal arch bar to be secured to the outer surfaces of the upper teeth with wire ligatures and provided with arms extending out of the mouth on each side for attachment to a plaster of paris headcap with straps or heavy elastics. By this means the upper jaw can be gradually

Symptoms and Diagnosis.—A depression is seen in the cheek on the side of the injury, just below the outer corner of the eye while lower down the cheek appears to be swollen. The entire side of the face may be so swollen and edematous as to mask the deformity. Diplopia may be present as a result of the depression of the floor of the orbit or of interference with the action of the ocular muscles. Subconjunctival ecchymosis is seen. Epistaxis usually occurs because of rupture of the mucosa of the maxillary sinus. The patient complains of numbness of the side of the nose and lip, owing to injury of the

* Ivey and Curtis: *Fractures of the Jaw*, Lea & Febiger, Publishers.

infraorbital nerve. Palpation reveals tenderness and irregularity of outline at four points over the zygomatic arch the junction of the malar with the frontal bone the lower rim of the orbit and where the malar bone joins the maxilla below. A ray examination to show the skull bilaterally in the vertical position will clearly outline the depressed malar bone. There may be difficulty in closing the mouth because of interference with the coronoid process.

Treatment consists in elevation of the depressed bone as early as possible. After two weeks this may be very difficult as union occurs rapidly and a permanent deformity may remain. Many methods of elevation have been advocated. The most efficient in the writer's hands is that suggested by Gilles which consists in lifting up the bone with a long flat elevator inserted through a small skin incision in the temporal region. The incision goes through the temporal fascia and the elevator slips down on the surface of the temporal muscle beneath the malar bone. The necessary amount of elevation can be controlled by placing the fingers on the cheek. No fixation is necessary. The incision is closed with a suture and leaves no visible scar since it is above the hair line.

Fracture of the nasal bones is also due to direct violence. The nasal bones may be thrust directly backward with or without comminution the septum being crushed or buckled beneath them or the bones may be displaced to one side.

Treatment—It is desirable to replace the bones if possible before swelling masks the deformity that is within the first few hours after injury. If treatment is postponed for two weeks or longer union may require dislodgment with a chisel. Fractures with little or no displacement do not require treatment. In recent cases it is generally possible to elevate the depressed bones by pushing them up with a closed pair of curved Kelly forceps inserted in the nostril and molding with the fingers externally. The use of intranasal splints is not as a rule satisfactory but the nose may be packed with gauze soaked in liquid petrolatum to aid fixation and to control hemorrhage. When the nasal bones tend to sag down a mattress suture of fine wire passed beneath them through the skin from side to side and tied over the lead plates

resting on the skin will often aid in preserving the prominence of the bridge of the nose. A recent case with lateral deviation can also be corrected by manipulation and recurrence of the deformity may be prevented by a scheme suggested by Blair. This consists in passing a fine wire with a long straight needle through the skin on the side of the deviation one end between the nasal bone and the nasal process of the maxilla and the other end below the lower border of the nasal bones. The ends of the wire cross the septum and come down into the vestibule of the mouth on the opposite side where they are attached to a premolar or a molar tooth. The loop of wire thus catches the outer angle of the nasal bone and holds the bridge over in place. The skin can be protected from the pressure of the wire by interposing a thin lead plate or by incising the skin between the points of insertion of the wire allowing it to bury itself against the bone.

FRACTURES OF HYOID BONE, THYROID AND CRICOID CARTILAGES, AND TRACHEA

Fracture of the hyoid bone occurred more frequently in earlier days when garroting was the favorite crime of violence rather than shooting with a modern sub-machine gun. Fortunately the great flexibility of the hyoid bone and surrounding structures gives it unusual protection. The incidence given in various statistics on fracture for this accident is about 0.002 per cent.

Diagnosis—The condition is very serious. There is a history of direct violence followed by severe pain in the throat, dysphagia, dysphonia, protrusion of the tongue produces suffocation. One or both of the cornua may be broken in the midline or near the junction with the body of the bone. The fragments generally penetrate the soft

tissue of the pharynx and profuse bleeding may occur. An x-ray examination made in a lateral oblique position is very helpful in giving a clear idea of the fracture and the relation of the fragments.

Treatment—One finger should be inserted into the mouth the other hand should be placed over the bone outside the neck and reduction obtained by manipulation. The patient should be kept absolutely quiet by means of sedatives. All blood saliva and exudate should be frequently and carefully removed by suction. Local application of ice to the neck adds to the patient's comfort and prevents swelling. It is most important to have him avoid swallowing for four or five days all feeding being done per rectum.

Fracture of Thyroid and Cricoid Cartilages—The thyroid is more often involved the ratio being about 4 to 1.

Diagnosis—There is a history of trauma—blows strangulations attempted hanging and falls being the common causes. The symptoms are very similar to those noted in connection with fracture of the hyoid bone. The pain on swallowing is extreme and there is usually more cyanosis. If there is not too much external edema abnormal mobility and displacements of the fragments can be observed.

Treatment—Immediate tracheotomy is essential. There is always edema of the mucous membrane. The blood and exudate should be removed by suction. It is usually safe to feed the patient by means of a nasal tube.

Fracture of the trachea is a very rare condition practically always associated with contusions and tears. Sudden violent extension of the neck (such as hanging or falls) is the usual etiologic factor.

Diagnosis—Pain frothy bloody expectoration and rapidly developing subcutaneous emphysema occurring in a patient subjected to recent trauma indicate the presence of a fractured trachea.

Treatment—The mortality which was formerly very high has been lessened by prompt tracheotomy and proper drainage produced by intelligent persistent use of suction. This should be followed as soon as possible by careful repair of the damaged tissues.

FRACTURES OF RIBS, CLAVICLE AND SCAPULA*

FRACTURES OF THE RIBS

Etiology and Pathology—Fractures of the ribs (Fig. 309) occur relatively frequently and tend to be multiple. Double fractures may occur. Because of the great elasticity of the ribs in children fractures of these bones are relatively rare before the age of puberty. Ribs may be fractured by either direct or indirect violence and occasionally by muscular action as from a cough or sneeze or from hearty laughing. In a fracture which is the result of direct violence the fragments tend to be driven inward into the pleural cavity and may not only rupture the parietal pleura but may also penetrate the visceral pleura and damage the lung. The fractures usually are complete and may be comminuted. The plane of the fracture may be transverse oblique or irregular. The first two ribs are rarely broken because they are protected by the shoulder and clavicle and the last two are rarely broken because their distal extremity is free and can be moved widely in any direction before a fracture can occur. The majority of fractures involve the fifth to the ninth ribs.

Diagnosis—There is usually a history of an injury either of a fall against some object or of a blow or crushing injury to the chest followed by a sharp pain in the side. The pain persists and the patient usually is able to localize it very exactly. If the fracture is at all severe the patient tends to lean to the affected side and to support and immobilize the area of the fracture with his hands. Deep breathing causes sharp pain in the chest. There may or may not be localized swelling and evidences of contusion and lacerations of the skin. The patient should first be asked to localize with his fingers the points of greatest pain. Then the surgeon should place one hand on the back of the chest well away from the painful area and the other hand on the front of the chest and gently compress the chest by springing the anterior extremity of the ribs inward. If there is a fracture this maneuver will elicit sharp pain at the site. Anteroposterior and

*This section contains quotations from Key and Connell's textbook entitled *Management of Fractures, Dislocations and Sprains*, ed. 3, St. Louis: C. V. Mosby Co., 1912.

lateral roentgenograms will generally reveal the fracture (Fig 309). Even if the x-ray picture shows no abnormality, the patient should be treated for fractured rib if the clinical observations indicate that a fracture is present. A stethoscopic examination of the chest should be made to determine whether or not there has been pleural or lung injury.

Complications. The complications are (1) massive collapse of the lung, (2) pneumothorax, (3) interstitial or surgical emphysema, (4) hemothorax, (5) hemorrhage into the lung, (6) empyema, (7) traumatic asphyxia or cyanosis and (8) paralytic

a severely crushed chest is always grave during the first few days after the injury.

Treatment.—In cases of severe injuries of the chest with multiple fractures of the ribs, the general condition of the patient should be considered first and surgical shock should be combated. The patient improves faster if kept in a sitting or semisitting position. Sufficient morphine should be given to keep him quiet. External heat should be applied in sufficient amounts to bring the body temperature to normal.

If extensive multiple fractures of the ribs are present and the side of the chest is curved

Fig 309—Roentgenogram showing fractures of the fifth to seventh ribs. Usually this type of fracture can be treated with a simple horizontal strapping.

Prognosis.—Fracture of a rib practically always heals despite the fact that it is not possible to immobilize the fragments. If the fragments are displaced, healing takes place with deformity and not infrequently synostosis may occur between two or more ribs. In spite of the deformity the functional result is practically always good. The general prognosis depends on the severity of the injury, including any complications which may arise and the general condition of the patient. In older persons the prognosis is less favorable than in the young, because the former are more apt to succumb to respiratory infections. The prognosis in the case of

in strapping, with adhesive tape is usually to be avoided since it serves to increase the pain and respiratory distress. It is always a good rule to remove the strapping immediately if the patient is not more comfortable and if the general condition is not better after the adhesive tape has been applied. In such cases no dressing at all or a heavy muslin swathe or elastic stockinet bandage may be used.

Most patients with a simple or minor multiple fracture of the ribs are more comfortable and do better if the chest is strapped (Fig 310). This is particularly true of fractures below the fourth rib. In fractures of

the upper four ribs, healing progresses almost as well without strapping, and sometimes the patient is more comfortable. In certain fractures of the upper ribs, vertical strapping over the shoulder and down the

old tape should, if possible, be left on for ten days or two weeks, since early removal and reapplication not only cause pain and discomfort to the patient, but also result in increased irritation of the skin. At the end

Fig 310—Strapping ribs. When the skin is tender it is better to bandage the entire chest tightly in exhalation *

Fig 311—Front and back views (a and b) showing the vertical method of strapping for fractures of the upper four ribs †

back may be of distinct advantage to the patient's comfort (Fig. 311).

At the end of four or five days, if the chest has been strapped, the adhesive tape will have become loose and rather inefficient. It should be reinforced by fresh tape over the old, applied in the same manner. The

of ten days or two weeks it will probably be necessary to remove the tape. This should not, however, be done until it is necessary

* Christopher—Minor Surgery, W. B. Saunders Co., Publishers

† Key and Conwell—The Management of Fractures, Dislocations and Sprains, C. V. Mosby Co., Publishers

New adhesive tape should be applied in the same manner after the skin has been washed with alcohol and ether. At the end of from fourteen to eighteen days strapping will in most cases not be necessary since the ribs will be fairly well immobilized by callus and the patient will be more comfortable without them. In obese women with large pendulous breasts it is usually best to hold up the breasts with a tight brassiere or muslin binder.

TRACTURES OF THE COSTAL CARTILAGES

Fractures of the costal cartilages tend to occur more frequently in young adults while fractures of ribs occur more frequently in persons over thirty years of age. One or more ribs may be separated from their articulation

or attempted reduction the chest should be strapped by cross strapping of adhesive tape.

TRACTURES OF THE STERNUM

Fracture of the sternum is a rare injury. It may occur as a result of direct violence as in blows on the front of the chest from crushing injuries or from hyperflexion injuries such as result in compression fractures of the spine.

Pathology.—The majority of the fractures occur in the body of the bone (gladiolus) near its junction with the manubrium. The line of fracture is usually transverse, but it may be oblique while vertical fractures are almost unknown. When displacement occurs the lower fragment is usually

Fig. 312.—Roentgenogram showing typical deformity in a fracture of the middle third of the clavicle.

tilage at the costochondral junctions the cartilage may be dislocated from its attachment to the sternum or it may be broken across at any point or two cartilages may be separated from one another. The symptoms are similar to those of a fracture of the rib except that the localizing symptoms point to a lesion in the area occupied by the costal cartilage. The lesion may not be visible in the x-ray picture.

If there is obvious dislocation with deformity attempts may be made to reduce the dislocation or displacement. The patient inspires fully while the shoulders are drawn backward by assistants and the surgeon manipulates the displaced cartilage and by direct pressure attempts to restore the normal contour of the chest. After the reduction

displaced forward and its upper end overrides the lower end of the upper fragment.

Diagnosis.—There is a history of injury to the chest with pain localized over the sternum. A moderate amount of swelling is present, and if displacement has occurred the swelling may be considerable. The patient tends to droop the head and shoulders forward; respiration is shallow and deep respiration and coughing or sneezing are accompanied by intense pain at the site of the fracture. On palpation it may be possible to feel the displaced fragments and determine the displacement. Mobility of the fragments may be observed during breathing. If a fracture of the sternum without displacement is suspected the diagnosis can be confirmed by an x-ray picture which should be taken.

in the lateral plane. It will show any displacement as well as the line of fracture.

Prognosis.—The prognosis is good since these fractures are through cancellous bone

front of the chest over the sternum. This position should be maintained for from two to three weeks, at the end of which time the patient may get up with a cross strapping

Fig 313—Adhesive dressing for fracture of the clavicle. Application of adhesive strip 1. This pulls the shoulder back, aiding approximation of overlapped fragments. The hand of the uninvolved side should remain on top of the head throughout the whole period of the application of the dressing.*

and tend to heal rapidly. Even if the fracture heals with overlapping, the functional prognosis is good, although there may be some visible deformity on the front of the chest.

Fig 314—Adhesive dressing for fracture of the clavicle. Felt pad and adhesive strip 2 being applied. This procedure prevents an exaggerated upward displacement of the proximal fragment.*

Treatment.—If there is no displacement of the fragments, the patient should simply be placed in bed with a small pillow under his shoulders and a small sand bag on the

Fig. 315—The cotton prevents coaptation of the skin surfaces and acts as a fulcrum to the arm and strip 4 in relieving any overlapping of the fragments.*

over a felt pad above the site of the fracture and a posterior figure of 8 bandage on the shoulder.

The posterior application of strip 3 is also shown.*

drawn backward. If necessary, traction should be used with countertraction on the feet.

With the patient in this position, the surgeon should attempt by downward pressure on the upper end of the lower fragment to push it backward into its normal position. If this is very painful the fractured area may be anesthetized by infiltration with novocain. If it is found to be impossible to reduce the displacement by the closed method, the fracture may be exposed (preferably under local anesthesia) and the depressed fragment levered up into place, but this is not always necessary for a good functional result. The after-treatment is the same as that described for fractures of ribs.

Fig 319—Adhesive dressing for fracture of the clavicle. The completed dressing showing the elbow flexed with the forearm against the chest and adhesive strip 4 horizontally crossing the arm and forearm end to end at the point where it commenced. Cotton should always be placed between the skin surface and the adhesive strips and the forearm.*

FRACTURES OF THE CLAVICLE

Etiology.—The clavicle is one of the most frequently broken bones in the body, and statistics show that it is involved in from 5 to 10 per cent of all fractures. This is especially true in childhood, when many of the fractures are incomplete and are often not recognized. The injury usually occurs as a result of a fall on the outstretched hand, elbow or shoulder, the latter being pushed violently inward against the chest.

Pathology.—The clavicle may be broken in any part. In the majority of cases the break occurs in the middle third just internal to the attachment of the coracoid ligament (Fig 312). In adults the fracture line

is usually oblique but it may vary from transverse to almost longitudinal and may take almost any direction. In older persons the bone is often comminuted. Complete fracture of the bone results in shortening with overriding of the fragments the shoulder drops downward forward and inward and the outer fragment goes with the shoulder. The sternomastoid muscle tends to pull the inner fragment upward and backward but its displacement is limited by the costo-clavicular ligament. When the outer third of the clavicle is fractured the lesion is usually a transverse break and as the outer fragment is fixed to the acromion and the inner fragment is bound to the coracoid there is little displacement unless this ligament is ruptured but the scapula may swing forward and cause an angular deformity at the site of the fracture.

Fig 320—Zimmer clavicular cross

Diagnosis—The patient assumes a characteristic attitude with the limb on the affected side supported by the other hand the head is inclined to the affected side with the chin rotated to the opposite side to release the tension of the sternomastoid muscle on the inner fragment. On inspection the shoulder is found to be normal in contour but it is lower than the one on the other side slightly closer to the midline of the body and displaced slightly forward. On palpation tenderness is noted over the site of the fracture and it is frequently possible to feel the prominent outer end of the inner fragment beneath the skin. In fractures without overriding or displacement the history of injury followed by disability in the arm and the location of the pain and point tenderness are usually sufficient to establish a diagnosis.

In children with incomplete fractures there may be no displacement and the history may be indefinite it simply having been noted by the parents that the child complained of pain or cried when lifted by the arm and did not use the arm normally. The shoulder may be normal to inspection but the child will usually be unable to raise the affected arm above the level of the shoulder and point tenderness may be elicited at the site of the fracture. There may be slight swelling over the fracture and the diagnosis can be confirmed by roentgenograms or some days later by the presence of a small amount of callus at the site of the fracture.

Treatment—The object of treatment is to obtain a satisfactory functional and cosmetic result to make the patient comfortable and to restrict his activity as little as necessary. In greenstick fractures in chil-

dren the clavicle is bowed forward and since the deformity tends to persist it should be corrected. This can be accomplished with the patient in the recumbent position by pressing backward at the apex of the deformity. A general anesthetic is administered and the deformity is corrected. Conwell's dressing (Figs 313-319) the modified Velpeur dressing or the posterior figure of 8 bandage is simple, comfortable and adequate and will suffice as a dressing in these cases.

In fractures with slight displacement in patients of any age except those who are quite fat or very old and feeble the adhesive dressing of Conwell is as comfortable and efficient as any. It should be worn for from three to five weeks followed by a sling for two weeks. The clavicular cross (Fig 320) is favored by many competent surgeons for

this type of case, but it is difficult to make comfortable if it is applied tightly enough to be efficient. In cases of fracture in fit or senile patients the axillary pad swathe and sling are useful. This dressing is not very efficient but it can be made fairly comfortable and gives a good function if and usually a good cosmetic result. It should be worn for from three to five weeks followed by a sling for two weeks. In fractures with marked displacement in any type of patient or fractures with mild or moderate displacement in young girls or women in whom a good cosmetic result is of importance removal by with lateral traction is the method of choice.

Treatment—As there is little tendency for the fragment to be displaced all that is necessary is to make the patient as comfortable as possible until the bone has healed. This is accomplished by immobilizing the shoulder and the soft parts over the scapula with an adequate criss cross strapping with adhesive tape over the scapula by fastening the arm to the chest with a pad placed in the axilla and by employing a sling for the wrist. Function is gradually resumed about four weeks after the injury and complete recovery is usually obtained.

B Fractures of the Spine of the Scapula—These fractures are practically always

Fig. 321.—*Cornell's lateral traction frame* for treating fractures of the clavicle, sternum, scapula and upper extremity when traction on the bed is indicated.

(Fig. 321) This will reduce practically any displacement and assure an almost perfect result in almost every case.

FRACTURES OF THE SCAPULA

A Fractures of the Body—Diagnosis is made from the history of an injury either directly over the bone or indirectly from force transmitted through the humerus followed by local pain, swelling, tenderness and usually an inability to raise the arm fully on the affected side. There is tenderness over the scapula. Fracture of the scapula may be overlooked or ignored because of the gravity of other injuries and the accompanying shock, surgical emphysema or pneumothorax.

the result of direct violence and are usually accompanied by a comminuted fracture of the body of the scapula. The diagnosis is established by the local tenderness and swelling with a palpable change in contour and the ability to detect loose fragments or false motion. There is little tendency to displacement but false motion and crepitus may be elicited.

Treatment—In these injuries also there is little or no tendency to displacement of the fragments and they are treated exactly as are fractures of the body of the bone.

C Fractures of the Acromion—By careful palpation along the outer portion of the spine the fracture line can be felt as an irregularity in the bone or located by the

presence of point tenderness. False motion may be obtained by manipulating the acromion or by pushing upward on the humerus while the scapula is fixed. When the fracture is lateral to the acromioclavicular joint there is little tendency for displacement of the small free fragment and a diagnosis must be based on the point tenderness and the inability to produce false motion of the tip of the acromion. Usually the small detached fragment cannot be palpated and an x-ray examination is necessary before the diagnosis is made.

Treatment—In fractures through the base without displacement and in those instances in which the fracture line lies lateral to the acromioclavicular joint the tip of the process

arm is abducted or actively adducted against resistance. False motion and crepitus can not always be obtained.

Treatment—A convenient and efficient method of treatment is to place a pad of saddlers felt 3 inches in diameter and 1½ inches thick over the fractured process. This is held in place by a strip of adhesive tape 3 inches wide which is started on the posterolateral aspect of the shoulder and pulled forward and downward across the pad and fastened around the opposite side of the chest. After the axilla is padded and the chest protected by a circular bandage the hand on the affected side is then placed on the opposite shoulder and immobilized in the third and fourth strips of Conwell's ad-

Fig. 523—Fluorogram showing a separation of the acromioclavicular articulation.

being detached a criss cross strapping should be applied over the deltoid muscle in such a manner that the adhesive tape which is pulled from below upward tends to force the fragment back in place. The arm is then immobilized by a circular swathe and sling as in fractures of the body. In fractures through the base of the acromion or through the acromioclavicular joint with flattening of the shoulder and dropping down of the detached fragment the condition is similar to an acromioclavicular lesion and the acromioclavicular adhesive dressing should be applied.

D Fractures of the Coracoid Process—The symptoms are swelling and tenderness over the process and localized pain when the

adhesive dressing or in a Velpau bandage. This dressing is worn for about three weeks and then the arm is carried in a sling for two weeks longer.

F Fractures of the Surgical Neck and Glenoid Cavity—**Diagnosis**—In a typical case of fracture of the neck of the scapula with tearing of the ligaments and marked displacement the lesion somewhat resembles that of a dislocation of the shoulder except that there is no fixation of the upper extremity. There is total inability to use the arm. Passive motion is not restricted by means of a push upward on the elbow the deformity can be reduced and crepitus may be obtained.

In fractures of the neck or glenoid in

which the ligaments remain intact the diagnosis is more difficult. Swelling and tenderness of the shoulder and prominence of the acromion are noted. In a fracture of the neck of the scapula if the inferior angle and body of the bone is grasped with one hand and the upper end of the humerus and coracoid process with the other false motion and crepitus may be demonstrated by manipulating one part of the bone while the other is immobilized. Fractures of the glenoid are to be suspected when pain and crepitus are elicited on slight rotation of the humerus. An x ray picture should always be taken if possible in cases of injury to the shoulder.

Fig. 323.—Type of ambulatory dressing which is useful for treatment of acromioclavicular separations.*

Treatment—In simple fractures through the neck of the scapula with relatively little damage to the ligaments with only slight downward displacement of the shoulder joint and with no involvement of the glenoid cavity a most satisfactory method of treatment is a slight modification of the acromioclavicular adhesive dressing. In fractures of the neck with considerable damage to the ligaments and downward displacement of the shoulder but no damage to the glenoid cavity an adhesive dressing should be tried but the results should be carefully checked

* Key and Conwell: The Management of Fractures, Dislocations and Sprains. C. V. Mosby Co. Philadelphia.

by x ray pictures and if the position of the fragments is not satisfactory the patient should be treated in recumbency with lateral traction. If the fracture line involves the glenoid cavity and if comminution and separation of the fragments are present the fracture must be treated with traction and with the arm in abduction preferably with the patient recumbent. The traction tends to pull the fragments of the glenoid cavity back into position and hold them there.

Prognosis—In fractures of the neck which do not involve the glenoid cavity a normal condition of the shoulder may be expected in three months unless there is severe damage to the soft parts and traumatic arthritis or periarthritis develops. These may prolong the disability indefinitely.

In fractures of the glenoid cavity without displacement a practically normal shoulder is usually obtained. If the bone is comminuted there is apt to be more or less limitation of motion together with occasional twinges of pain from time to time especially during changes of weather.

H. FARLEY CONWELL

FRACTURES OF THE UPPER ARM

Success in the treatment of a fracture of the upper arm is largely dependent on the following considerations:

1. A careful yet rapid preliminary examination of the patient must be made in order to ascertain not only the location and extent of the fracture of the upper extremity but the degree of injury to the soft tissues, the signs of associated pathologic conditions elsewhere and the presence or absence of shock.

2. The surgeon must be able to evaluate quickly the importance of these physical findings and considering the patient's age, occupation and social status to decide how strenuous an effort should be made to bring about an accurate alignment of the broken bone and whether in the attainment of this end conservative or radical (operative) methods of treatment should be employed.

3. In the reduction of the fracture it must be borne in mind that the position of the bone fragments is dependent on two factors: the direction and degree of the force causing the injury and the effect of pull on the muscles.

humerus (Fig 323 C) is occasionally met with in a child or young adult, and it has been emphasized by Howard and Eloesser that in the second decade of life it is particularly prone to occur because at that period the epiphyseal line is the weakest point in the upper third of the bone. The mechanism of its production is similar to that for fracture through the surgical neck (Fig 323 D) and the clinical manifestations seldom allow a differentiation to be made without the aid of an x-ray picture. In the treatment it must be remembered that accurate anatomical contact is of paramount importance because one is dealing with the epiphysis which unites it and an incomplete reduction may result in a noticeable disturbance in the growth of the bone. If the condition is treated early enough this is usually accomplished without much difficulty by traction under anesthesia with direct pressure on the upper end of the long fragment and during the maneuver one may actually feel the upper end of the shaft slip back into place. Once the separation is properly reduced and checked with the x-ray picture, the natural convexity of the under surface of the epiphysis tend to prevent any chance of position during the rather brief period of bone repair (from four to six weeks with the arm abducted in a plaster cast or Thomas splint). Abduction may be necessary to maintain the position of the fragments.

B. Fractures through the surgical neck of the humerus—the portion of the bone between the tuberosities and the attachment of the pectoralis major muscle assume a role of major importance because of their great frequency and the difficulties that sometimes accompany their treatment. They are seen in children and young adults particularly rarely in those of advanced years. In the report of a series of 500 consecutive fractures of the humerus published by Cubbins and

the long distal one being pulled inward by the strong action of the pectoralis major latissimus dorsi and teres major and upward by the long head of the triceps and coracobrachialis muscles. Clinically one observes great swelling just below the shoulder and deviation inward of the axis of the arm crepitation on movement of the shaft and failure of rotation of the head of the bone. Not infrequently the upper end of the lower fragment can be palpated with the fingers in the axilla.

As to the treatment in these cases a great deal of controversy has arisen as to the proper course to pursue. Bohler and most other surgeons take the stand that reduction can be satisfactorily made by abduction of the arm to 45 degrees and traction in the line of the upper arm, this position being maintained during the necessary period of bone repair (from eight to twelve weeks) either by a properly applied aeroplane splint if the patient is ambulatory or a Thomas splint with adhesive tape traction if the patient is kept in bed. Howard and Eloesser on the other hand after a long series of experiments with fractures artificially produced on the cadaver and as a result of wide clinical experience take the position that the short upper bone fragment in these injuries is scarcely abducted at all because of the splinting action of the long tendon of the biceps (when intact) and the uniform portion of the periosteum (Fig 324 C and D). The use of local anesthesia, reduction by downward traction in line with the upper fragment and immobilization by means of an ambulatory type of splint with the upper arm close to the body has been very successful in their hands. The abducted position of the arm has one great advantage, namely that it relaxes the great muscles about the shoulder and preserves the position that is the most difficult to regain after the arm has been close to the side for a long

period. Fractures of the shaft of the humerus comprising about one half of all fractures of the upper arm offer many interesting problems because of the wide variation in pathology, the likelihood of involvement of the musculospiral nerve and the ability of delayed or non union. Direct rather than indirect violence is respon-

portion of the capsule of the joint. There is severe bruising of the muscles, great effusion of blood over a large area and consequently much swelling about the shoulder and upper arm. The treatment in such a case presents a major problem and often taxes the ability and judgment of the surgeon. Though Bohler has stated that he has been almost uniformly successful in the reduction of the head by manipulation under local anesthetic, most surgeons feel that without open operation it is rarely possible to overcome this displacement of the head and bring about satisfactory contact through the frac-

ture line. A direct blow and occasionally it is pulled loose by severe muscle violence. The signs of injury are manifest by local tenderness and swelling beneath the acromion process in the axilla. The patient is unable to rotate the upper arm outwardly and sometimes by actual palpation of the displaced fragment. The diagnosis must be verified by x-ray pictures taken at the proper angle (Fig. 325 A). The treatment of these injuries has for its object an accurate contact of the broken surfaces in order to preserve the function of rotation, prevent excessive callus formation and obviate a permanently painful

Fig. 325.—Drawings made from x-ray films. A, Unusually good example of an isolated fracture of the greater tuberosity. B, fracture of the head at the level of the epiphyseal line in a boy of ten years. Open reduction was obtained after failure of satisfactory alignment by means of manipulation. C and D, fracture through the surgical neck just beyond the epiphyseal line in a boy of ten years. Open reduction was obtained after failure of satisfactory alignment by means of manipulation. E and F, pathological fracture through a bone cyst in a young girl at the femoral site—the upper third of the humerus.

ture line. The alignment of the bone, however secured, must be maintained with the arm in the abducted position either by means of a plaster cast or a suitable traction apparatus for a period of from eight to twelve weeks. A gradual change in the angle of abduction and the early use of active motion will do much to preserve the range of mobility at the shoulder joint.

Its success is largely dependent therefore on the absence of an associated dislocation because if a dislocation is present the correct position of the arm during the period of bone repair (abduction and external rotation) is not favorable for healing of a tear in the inferior portion of the joint capsule and must be modified to meet these conditions. In rare instances in which very accurate function of the shoulder is of great importance (i.e., of a baseball pitcher) open operation may be indicated after conservative measures have failed.

4 Separation of the upper epiphysis of the

cles which insert on the proximal and distal fragments. One would be wise in observing the cardinal principle that the fragment which can be controlled (distal) must be placed and maintained in line with and in contact with if possible the fragment over which the surgeon can have little or perhaps no control (proximal).

4 In the effort to accomplish this objective the trauma will be minimized if the patient is seen early before the swelling of the soft parts has made palpation of the bony landmarks difficult. Moreover the type of apparatus to be employed for traction and immobilization must be determined in the light of the patient's age, his general condi-

tuberosities without much gross displacement are very frequently seen. They occur particularly in elderly persons with brittle bones and are the result of a slight fall on either the elbow or the arm in the abducted position. There is considerable swelling about the shoulder joint on movement and local tenderness on palpation. Because of the frequent impaction the head is apt to rotate with the shaft and no crepitation may be felt. Conservation in treatment is the wise policy as the bone will readily unite and fair use of the shoulder may be preserved if a simple sling is worn or if the arm is abducted for two or three weeks in a comfortable aeroplane spine. I have used the

Fig. 324.—Drawings made from x-ray films. A and B Fracture through the surgical neck brought into excellent alignment by rather marked abduction of the arm and the use of a Thomas splint. C and D fracture through the surgical neck with little abduction of the upper fragment. Good alignment was obtained with the arm in moderate abduction. E and F example of a rare injury, severe fracture-dislocation at the upper end of the humerus. Good reduction and alignment were secured with the application of a short Lane plate.

tion and the extent of bruising or laceration of the soft parts, the surgeon keeping in mind the necessity for the preservation of the patient's general health and the use of active motion of the extremity as early as is consistent with safety.

5 And lastly important is the selection of the proper type of apparatus; it is surpassed in importance by the manner in which the apparatus is applied and the daily attention paid to it by the attending surgeon.

A Fractures of the upper end of the humerus present themselves clinically in one of four ways:

1 Fractures through the head and anatomical neck into the cancellous area of the

wide elastic tetra bandage in conjunction with the sling and have found it most satisfactory. It is very important that this bandage and sling be removed once each week so that the skin can be carefully washed with soap and water and all crevices powdered with talc. Active movements at the shoulder and elbow are begun very early.

2 Severe fracture dislocations of the upper end of the bone are rare accidents occurring as a rule in strong laboring men as a result of a fall from a height on the abducted arm (Fig. 324 F and I). The head of the bone may be sheared off cleanly across the anatomical neck by impingement against the lower margin of the glenoid (Speed) as it is driven through the tear in the inferior

portion of the capsule of the joint. There is severe bruising of the muscles, great effusion of blood over a large area and consequently much swelling about the shoulder and upper arm. The treatment in such a case presents a major problem and often taxes the ability and judgment of the surgeon. Though Bohler has stated that he has been almost uniformly successful in the reduction of the head by manipulation under local anesthetic, most surgeons feel that without open operation it is rarely possible to overcome this displacement of the head and bring about satisfactory contact through the frac-

ture blow and occasionally it is pulled loose by severe muscle violence. The signs of injury are manifest by local tenderness and swelling beneath the acromion process, inability of the patient to rotate the upper arm outwardly and sometimes by actual palpation of the displaced fragment. The diagnosis must be verified by x-ray pictures taken at the proper angle (Fig. 325 A). The treatment of these injuries has for its object an accurate contact of the broken surfaces in order to preserve the function of rotation, prevent excessive callus formation and obviate a permanently painful

Fig. 325—Drawings made from x-ray films. A Unusually good example of an isolated fracture of the greater tuberosity. B fracture of the humerus at birth. C and D fracture through the surgical neck just beyond the epiphyseal line in a boy of ten years. Open reduction was obtained after failure of satisfactory alignment by means of manipulation. E and F pathologic fracture through a bone cyst in a young girl at the favorite site—the upper third of the humerus.

ture line. The alignment of the bone, however secured, must be maintained with the arm in the abducted position either by means of a plaster cast or a suitable traction apparatus for a period of from eight to twelve weeks. A gradual change in the angle of abduction and the early use of active motion will do much to preserve the range of mobility at the shoulder joint.

3 The greater tuberosity of the humerus, forming the bony prominence of the shoulder, may be broken off in several ways. It occurs usually during a dislocation of the joint; sometimes it is clipped off by a glanc-

shoulder. Its success is largely dependent therefore on the absence of an associated dislocation, because if a dislocation is present the correct position of the arm during the period of bone repair (abduction and external rotation) is not favorable for healing of a tear in the inferior portion of the joint capsule and must be modified to meet these conditions. In rare instances in which very accurate function of the shoulder is of great importance (i.e., of a baseball pitcher), open operation may be indicated after conservative measures have failed.

4 Separation of the upper epiphysis of the

humerus (Fig 323 C) is occasionally met with in a child or young adult and it has been emphasized by Howard and Lloesser that in the second decade of life it is particularly prone to occur because at that period the epiphyseal line is the weakest point in the upper third of the bone. The mechanism of its production is similar to that for fracture through the surgical neck (Fig 323 D) and the clinical manifestations seldom allow a differentiation to be made without the aid of an x-ray picture. In the treatment it must be remembered that accurate anatomical contact is of paramount importance because one is dealing with the epiphysis which unites last and an incomplete reduction may result in a noticeable disturbance in the growth of the bone. If the condition is treated early enough this is usually accomplished without much difficulty by traction under anesthesia with direct pressure on the upper end of the long fragment and during the maneuver one may naturally feel the upper end of the shaft slip back into place. Once the separation is properly reduced and checked with the x-ray picture the natural convexity of the under surface of the epiphysis tends to prevent any change of position during the rather brief period of bone repair (from four to six weeks with the arm abducted in a plaster cast or Thomas splint). Abduction may be necessary to maintain the position of the fragments.

B Fractures through the surgical neck of the humerus. The portion of the bone between the tuberosities and the attachment of the pectoralis major muscle assume a role of major importance because of their great frequency and the difficulties that sometimes accompany their treatment. They are seen in children and young adults particularly rarely in those of advanced years. In the report of a series of 500 consecutive fractures of the humerus published by Cubbins and Scuderi 154 were through the surgical neck. The mechanism of production is almost invariably a fall on the abducted arm the force being insufficient to produce a dislocation of the head. The displacement of the fragments except in rare cases with impaction is usually quite characteristic (Fig 324 A and B) the short upper one being abducted by the supraspinatus muscle and

the long distal one being pulled inward by the strong action of the pectoralis major latissimus dorsi and teres major and upward by the long head of the triceps and coracobrachialis muscles. Clinically one observes great swelling just below the shoulder a deviation inward of the axis of the arm crepitation on movement of the shaft and failure of rotation of the head of the bone. Not infrequently the upper end of the lower fragment can be palpated with the fingers in the axilla.

As to the treatment in these cases a great deal of controversy has arisen as to the proper course to pursue. Bohler and most other surgeons take the stand that reduction can be satisfactorily made by abduction of the arm to 45 degrees and traction in the line of the upper arm this position being maintained during the necessary period of bone repair (from eight to twelve weeks) either by a properly applied aeroplane splint if the patient is ambulatory or a Thomas splint with adhesive tape traction if the patient is kept in bed. Howard and Lloesser on the other hand after a long series of experiments with fractures artificially produced on the cadaver and as a result of wide clinical experience take the position that the short upper bone fragment in these injuries is scarcely abducted at all because of the splinting action of the long tendon of the biceps (when intact) and the untorn portion of the periosteum (Fig 324 C and D). The use of local anesthesia reduction by downward traction in line with the upper fragment and immobilization by means of an ambulatory type of splint with the upper arm close to the body has been very successful in their hands. The abducted position of the arm has one great advantage namely that it relaxes the great muscles about the shoulder and preserves the position that is the most difficult to regain after the arm has been close to the side for a long time.

C Fractures of the shaft of the humerus comprising about one half of all fractures of the upper arm offer many interesting problems because of the wide variation in pathology the likelihood of involvement of the musculospiral nerve and the possibility of delayed or non union. Direct force rather than indirect violence is respon-

sible for most fractures through the shaft. The fracture may be simple or compound, transverse, oblique, spiral or comminuted. The soft parts may be intact or badly torn, and often many pieces of lead are present. It must not be forgotten, also, that the shaft of the bone is a favorite site for bone cyst (Fig. 325, E and F), metastatic carcinoma (Fig. 326, C), sarcoma and osteomyelitis, and any one of these may predispose to the so-called "spontaneous fracture" by very little force. The degree of displacement is determined largely by the amount of comminution, the direction of the breaking force and the effect of muscle pull but a rather

traying exactly the fracture line and the degree of comminution. Of greatest importance is the evidence of concomitant injury of the neighboring large vessels and nerves, and it cannot be too strongly emphasized that in the preliminary examination of the extremity, note must be made of the presence or absence of wrist drop, for if this is first observed after reduction has been made, an embarrassing controversy may arise as to the cause of its production. The musculospiral nerve hugs the bone very closely as it passes spirally along the middle third of the bone (Fig. 327) and may be bruised or torn by the force of impact, by the sharp edges of

Fig. 326.—Drawings made from x-ray films A and B, spiral fracture in a girl of twenty-two years, injured by a fall while skating, showing partial involvement of the musculospiral nerve. Good alignment was obtained by traction in a Thomas splint. C pathologic fracture through the middle third at the site of metastasis from a hypernephroma in a woman aged forty-eight. D, intermedullary bone graft from the tibia in a case of non-union from the interposition of soft parts.

typical dislocation of fragments usually presents itself, depending on whether the break is above or below the insertion of the deltoid muscle. In the former instance, the proximal fragment will be drawn toward the body by the pectoralis major, latissimus dorsi and teres major; in the latter instance it will be directed outward by the strong abducting force of the deltoid muscle. Abnormal mobility is usually outspoken, and there is crepitation unless interposition of soft parts exists.

The diagnosis of these injuries is very easy, because the deformity is evident and the roentgenogram is only of value in por-

traying exactly the fracture line and the degree of comminution. Of greatest importance is the evidence of concomitant injury of the neighboring large vessels and nerves, and it cannot be too strongly emphasized that in the preliminary examination of the extremity, note must be made of the presence or absence of wrist drop, for if this is first observed after reduction has been made, an embarrassing controversy may arise as to the cause of its production. The musculospiral nerve hugs the bone very closely as it passes spirally along the middle third of the bone (Fig. 327) and may be bruised or torn by the force of impact, by the sharp edges of the broken fragments or during the manipulation incident to reduction, producing in either case a partial or complete paralysis, as evidenced by a wrist drop and inability to extend the proximal row of phalanges. All efforts at reduction therefore must be carried out as gently as possible, in the hope that the periosteum along the back of the shaft will remain intact, not only to serve as a splint for the bone (as pointed out by Cubbins) but also as a protection for the nerve. If open operation is necessary, the position of this nerve should be constantly kept in mind.

The treatment of fractures of the shaft

humerus (Fig 325 C) is occasionally met with in a child or young adult and it has been emphasized by Howard and Eloesser that in the second decade of life it is particularly prone to occur because at that period the epiphyseal line is the weakest point in the upper third of the bone. The mechanism of its production is similar to that for fracture through the surgical neck (Fig 325 D) and the clinical manifestations seldom allow a differentiation to be made without the aid of an x-ray picture. In the treatment it must be remembered that accurate anatomical contact is of paramount importance because one is dealing with the epiphysis which unites last and an incomplete reduction may result in a noticeable disturbance in the growth of the bone. If the condition is treated early enough this is usually accomplished without much difficulty by traction under anesthesia with direct pressure on the upper end of the long fragment and during the maneuver one may actually feel the upper end of the shaft slip back into place. Once the separation is properly reduced and checked with the x-ray picture the natural convexity of the under surface of the epiphysis tends to prevent any change of position during the rather brief period of bone repair (from four to six weeks with the arm abducted in a plaster cast or Thomas splint). Abduction may be necessary to maintain the position of the fragments.

B Fractures through the surgical neck of the humerus the portion of the bone between the tuberosities and the attachment of the pectoralis major muscle assume a role of major importance because of their great frequency and the difficulties that sometimes accompany their treatment. They are seen in children and young adults particularly rarely in those of advanced years. In the report of a series of 500 consecutive fractures of the humerus published by Cubbins and Senderi 154 were through the surgical neck. The mechanism of production is almost invariably a fall on the abducted arm the force being insufficient to produce a dislocation of the head. The displacement of the fragments except in rare cases with impaction is usually quite characteristic (Fig 324 A and B) the short upper one being abducted by the supraspinatus muscle and

the long distal one being pulled inward by the strong action of the pectoralis major latissimus dorsi and teres major and upward by the long head of the triceps and coracobrachialis muscles. Clinically one observes great swelling just below the shoulder a deviation inward of the axis of the arm crepitation on movement of the shaft and failure of rotation of the head of the bone. Not infrequently the upper end of the lower fragment can be palpated with the fingers in the axilla.

As to the treatment in these cases a great deal of controversy has arisen as to the proper course to pursue. Bohler and most other surgeons take the stand that reduction can be satisfactorily made by abduction of the arm to 45 degrees and traction in the line of the upper arm this position being maintained during the necessary period of bone repair (from eight to twelve weeks) either by a properly applied aeroplane splint if the patient is ambulatory or a Thomas splint with adhesive tape traction if the patient is kept in bed. Howard and Eloesser on the other hand after a long series of experiments with fractures artificially produced on the cadaver and as a result of wide clinical experience take the position that the short upper bone fragment in these injuries is scarcely abducted at all because of the splinting action of the long tendon of the biceps (when intact) and the union portion of the periosteum (Fig 324 C and D). The use of local anesthesia reduction by downward traction in line with the upper fragment and immobilization by means of an ambulatory type of splint with the upper arm close to the body has been very successful in their hands. The abducted position of the arm has one great advantage namely that it relaxes the great muscles about the shoulder and preserves the position that is the most difficult to regain after the arm has been close to the side for a long time.

C Fractures of the shaft of the humerus comprising about one half of all fractures of the upper arm offer many interesting problems because of the wide variation in pathology the likelihood of involvement of the musculospiral nerve and the possibility of delayed or non union. Direct force rather than indirect violence is respon-

sible for most fractures through the shaft. The fracture may be simple or compound, transverse, oblique, spiral or comminuted. The soft parts may be intact or badly torn, and often many pieces of lead are present. It must not be forgotten, also, that the shaft of the bone is a favorite site for bone cyst (Fig. 325, E and F), metastatic carcinoma (Fig. 326, C), sarcoma and osteomyelitis, and any one of these may predispose to the so-called "spontaneous fracture" by very little force. The degree of displacement is determined largely by the amount of comminution, the direction of the breaking force and the effect of muscle pull but is rather

traying exactly the fracture line and the degree of comminution. Of greatest importance is the evidence of concomitant injury of the neighboring large vessels and nerves, and it cannot be too strongly emphasized that in the preliminary examination of the extremity, note must be made of the presence or absence of wrist drop, for if this is first observed after reduction has been made, an embarrassing controversy may arise as to the cause of its production. The musculospiral nerve hugs the bone very closely as it passes spirally along the middle third of the bone (Fig. 327) and may be bruised or torn by the force of impact, by the sharp edges of

Fig. 326.—Drawings made from x-ray films. A and B, Spiral fracture in a girl of twenty six years, injured by a fall while skating, showing partial involvement of the musculospiral nerve. typical dislocation of fragments usually presents itself, depending on whether the break is above or below the insertion of the deltoid muscle. In the former instance, the proximal fragment will be drawn toward the body by the pectoralis major, latissimus dorsi and teres major; in the latter instance it will be directed outward by the strong abducting force of the deltoid muscle. Abnormal mobility is usually outspoken, and there is crepitation unless interposition of soft parts exists.

The diagnosis of these injuries is very easy, because the deformity is evident and the roentgenogram is only of value in por-

traying exactly the fracture line and the degree of comminution. Of greatest importance is the evidence of concomitant injury of the neighboring large vessels and nerves, and it cannot be too strongly emphasized that in the preliminary examination of the extremity, note must be made of the presence or absence of wrist drop, for if this is first observed after reduction has been made, an embarrassing controversy may arise as to the cause of its production. The musculospiral nerve hugs the bone very closely as it passes spirally along the middle third of the bone (Fig. 327) and may be bruised or torn by the force of impact, by the sharp edges of the broken fragments or during the manipulation incident to reduction, producing in either case a partial or complete paralysis as evidenced by a wrist drop and inability to extend the proximal row of phalanges. All efforts at reduction therefore must be carried out as gently as possible, in the hope that the periosteum along the back of the shaft will remain intact, not only to serve as a splint for the bone (as pointed out by Cubbins) but also as a protection for the nerve. If open operation is necessary, the position of this nerve should be constantly kept in mind.

The treatment of fractures of the shaft

involves such a variety of problems that only the basic principles can be presented here. Many surgeons like Bohler are satisfied to reduce and immobilize most of these fractures whatever their level with the arm

Fig. 327—Anterior view of the right arm showing the relationship of the axillary and musculospiral nerves to the elements from this drawing it may be readily seen how the axillary nerve and with it the circumflex vessels may be injured in association with dislocations at the shoulder and fractures of the surgical neck. The musculospiral nerve because of its close proximity to the shaft in its middle third is particularly prone to injury when there is a fracture in this portion of the bone and to inclusion in a callus during the period of bone repair.

in the abducted position taking pains to prevent inward rotation of the distal fragment and to make free use whenever possible of the ambulatory aeroplane type of splint. Others prefer to leave the arm close

to the side taking advantage of the natural adducted position of the upper fragment and the traction effect of the weight of the arm in this position. For children we have made frequent use of the same type of skeletal traction for fractures of the shaft as for the common fractures in the supracondylar area. This is illustrated in figure 328. The degree of abduction can be readily changed to meet all conditions. Very severe injuries particularly the compound fractures with extensive laceration of the soft parts are unquestionably best treated after debridement with the patient in the recumbent position.

Fig. 328—Skeletal traction by means of a small screw in the humerus just distal to the olecranon process.

sion making use of the Thomas splint or the extension apparatus of Bardenheuer with moderate abduction of the upper arm combined with right angle flexion of the forearm. Ambulatory treatment in any case follows naturally as soon as the repair of the bone permits active motion of the shoulder and elbow. Those fractures through the lower third of the bone where the shaft broadens out to meet the condyles are best handled with the patient up and about with the upper arm close to the body, the elbow flexed to a right angle and the forearm in strong pronation (Bohler).

One of the most common and distressing

where the humerus takes a distinct forward bend. The fracture line does not enter the joint (Fig 332).

Etiology—This fracture occurs predominantly in children. About four fifths of them occur in children under ten years of age and nine tenths in persons under twenty. There are two varieties of this fracture. The classical one is the "extension" type. It occurs

Fig 330—Posterior views of the bones of the elbow joint. *A* In right angled flexion. *B* In full normal extension. Note that in extension the tip of the olecranon approaches the internal condyle.*

as the result of a fall on the outstretched hand. The more unusual or "flexion" type occurs as the result of a fall on the flexed

arm beneath the biceps tendon. The forearm looks short and flexion is limited. Swelling and bleb formation are marked.

Fig 331—Diagram showing the relation of the bony points of the elbow. *A* Right angled position. *B* acutely flexed position. Note the relative position of the condyle and the tip of the olecranon in each.*

elbow. This fracture is most often seen in adults, as children usually fall on the outstretched hand rather than on the elbow.

Diagnosis—In the "extension" type the line of fracture passes obliquely from behind downward and forward, the distal frag-

ment being displaced backward and upward usually with internal rotation. The distal end of the upper fragment is felt as a prominence beneath the biceps tendon. The forearm looks short and flexion is limited. Swelling and bleb formation are marked.

* LANGE, *Fractures of the Humerus, Radius and Ulna*. D. Appleton Century Co., Publishers.

and backward. Impaction is rare, and any lateral displacement is of the lower fragment outward. If the fracture is compound, the

Fig 332—Supracondylar fracture of the humerus in a child. Note the typical deformity and the soft tissue thickening through the elbow. This is the "extension" or common type.

wound is made by the lower end of the upper fragment.

Dislocation is ruled out by the normal relation of the bony landmarks and the imp-

act of the head of the radius or posterior dislocation at the elbow. Nerve injury may be present.

Diacondylar Fractures.—The etiology of these fractures is similar to that of supracondylar fractures, but the fracture line is slightly lower. They are not so notably confined to childhood as the supracondylar type and are only about one fifth as common. The line of fracture is above the epiphyseal line passing through the coronoid and olecranon fossae, and is partially intra-articular. The swelling is thus greater than in supracondylar fractures. In general, the complications are similar to those encountered in supracondylar fractures.

Intercondylar, T or Y Fractures (Condylar).—Whereas the above mentioned fractures are most common in children, the atypical or T or Y fractures are seen mostly in adults. They occur infrequently.

Etiology.—These conditions are usually the result of severe trauma from a fall on the flexed elbow, forcing the olecranon between the condyles, which then break loose from the shaft. The comminution is pronounced when caused by a crushing force.

Diagnosis.—Usually great swelling, discoloration and deformity (shapeless elbow)

Fig 333—T or Y fracture involving the condyles. This fracture usually results from a fall on the elbow, most often in adults.

ness of the arm. In dislocation the forearm is held in rigid semiflexion. These fractures are occasionally complicated by other injuries around the elbow, especially fracture

are noted, with mobility of the condyles on each other and on the shaft. Impaction does not exist. Crepitus is present unless joint swelling or interposition of soft parts pre-

vents The distance between the condyles is increased The diagnosis is made definitely only by means of roentgenograms (Fig 333)

Fractures of the condyles are almost as common as the supracondylar fractures The external condyle is more often fractured than the internal condyle In external condylar fractures the fragment usually includes the external condyle the external epicondyle and the capitellum the line of fracture extending upward and outward from the trochlea The fragment in internal condylar fractures includes also as a rule the trochlea and the internal epicondyle The typical line of fracture runs from the lateral side of the trochlea upward and inward above the internal epicondyle

Etiology—Fracture of the external condyle may be produced by a fall on the outstretched hand the force passing through the radius to the capitellum by a fall on the flexed and abducted elbow the olecranon being forced against the capitellum or by direct force The internal condyle is typically fractured by a fall on the adducted and flexed elbow the olecranon being forced against the trochlea It may also be fractured by direct force Children usually fall on the outstretched hand rather than the elbow and thus suffer external rather than internal condylar fractures

Diagnosis—In external condylar fractures greater pain and swelling on the outer aspect of the elbow are noted The external condyle is movable with crepitus if swelling is not too great It has lost its normal relationship in the olecranon and internal condyle Flexion and supination of the forearm is limited and painful The condition may be complicated by rotation of the fragment so that the capitellum looks upward and not forward These fractures being due to the same type of injury as supracondylar and discondylar fractures are subject to the same type of complications

In internal condylar fractures the pain and swelling are greater on the inner aspect of the elbow Because of the loss of support of the internal condyle the forearm swings inward losing its carrying angle and its relationship to the shaft and olecranon is destroyed Action of the pronator and superficial flexor muscles of the forearm is limited

and painful There may be injury to the ulnar nerve This fracture may be complicated by fracture of the olecranon

Fractures of the Epicondyles—Fracture of either epicondyle is rare but that of the internal epicondyle is more common than that of the external epicondyle The internal one is frequently associated with posterior dislocation at the elbow

Diagnosis—Fractures of the epicondyles when uncomplicated are of no great moment Fractures of the internal epicondyle do not enter the joint while those of the external epicondyle may do so In the e fractures localized pain tenderness swelling mobility and crepitus are noted In the fractures of the external epicondyle there is painful flexion and supination of the forearm due to muscle attachment With the internal epicondyle action of the pronator and superficial flexor muscles of the forearm is limited and painful The fragment of either epicondyle will be displaced downward by muscle pull The possibility must be borne in mind of mistaking for a fracture the normally persisting epiphyseal line as seen in the roentgenogram

Fracture of the internal epicondyle is not infrequently complicated by injury to the ulnar nerve because of its close relation hip

Fractures of the capitellum are rare and occur as the result of indirect force on the capitellum through the head of the radius The fracture is entirely intra articular and is similar in etiology and symptoms to a fracture of the head of the radius except that the head of the radius moves with the shaft The diagnosis is usually made roentgenographically

Fractures of the Trochlea—This is an extremely rare fracture It occurs as a result of indirect force on the trochlea through the ulna This fracture like that of the capitellum is intra articular and hence associated with joint symptoms chiefly swelling tenderness and pain together with joint effusion and limitation of motion Here also the diagnosis is usually made by roentgenogram

Epiphyseal Separations of Lower End of Humerus—At birth the entire shaft of the humerus is ossified while the two extremities are cartilaginous There are four or more nuclei of ossification in the lower extremity which appear as follows (Fig 334)

Lower Epiphysis

- 1 Nucleus for capitellum and part of side of trochlea
- 2 Nucleus for internal epicondyle
- 3 Nucleus for trochlea There may be more than one
- 4 A very small and insignificant nucleus for the external epicondyle

Fig. 334—A. The anterior-posterior view shows the epiphyseal centers for the capitellum, the trochlea, the internal epicondyle, and the external epicondyle for the lower end of the humerus and the center for the head of the radius. B. The lateral view shows the center for the head of the radius and the olecranon center. C. Note the three concentric circles, the largest and smallest being the trochlea and the intermediate one the capitellum. This appearance indicates a true lateral view.

Thus the lower end of the humerus lacks a single common epiphysis similar to those of other long bones. Instead ossification pro-

ceeds from several distinct epiphyseal centers which unite with the shaft at different age periods. Any of these epiphyses may be-

come separated as a result of trauma during the vulnerable period.

Up to the age of ten, about one fifth of the growth of the humerus is believed to come from the lower epiphysis. After this time there is little growth from this epiphysis; hence its separation has little effect on the length of the bone.

Separation of the entire lower humeral epiphysis is rare but possible up to the age of four or five. It is really a cartilage separation of the entire end containing the four developing centers. With respect to etiology,

internal epicondylar epiphysis remains separate and unites with the shaft during the nineteenth year. This would indicate that between the ages of thirteen and seventeen the three lateral epiphyses separate as a group. It does not mean, however, that this cannot occur before the age of thirteen, as the majority of such injuries are found in children less than thirteen years of age.

Cotton states that at about thirteen years a trochlear ossification occurs which unites to the shaft soon after and thus explains the occasional separation in one group of the

Fig. 335.—Elisson's lateral hyperflexion position and dressing. The plaster to support the wrist was omitted for photographic purposes.

mechanism, symptoms and deformity, it does not differ from a supracondylar fracture except that the lesion is seen to be lower in the roentgenogram.

These various epiphyseal centers may be separated individually until they fuse with one another.

Epiphyseal Separation of External Condyle.—This term is used to denote the three lateral epiphyseal centers, namely, the external epicondyle, the capitellum and the trochlea. Some writers consider that these centers comprise the lower humeral epiphysis since they commonly separate as a group, leaving the internal epicondyle intact (Seudder). This is one of the most common injuries of the lower end of the humerus. It is the consensus of opinion that the three lateral epiphyseal centers unite to form a single bony epiphysis during the thirteenth year, which fuses with the shaft in the sixteenth to seventeenth year. The

external condyle, capitellum and a small portion of the trochlea but not the entire trochlea.

The joint capsule is attached above the epiphyseal line so as to enclose all but the internal epicondyle. Epiphyseal separations, therefore, are intra-articular; so unless the capsular ligament is torn, it tends to prevent any great displacement.

Epiphyseal Separation of the Internal Epicondyle.—The internal epicondylar epiphysis is formed from a separate ossification center which is displaced internally by the downward growth of the diaphysis, so that by the thirteenth year it is a distinct detached epiphyseal particle not communicating with the joint. It fuses with the shaft during the nineteenth year.

Separation of the internal epicondyle occurs more often than that of the external epicondyle, since the latter usually separates with the capitellum and trochlea as

mentioned previously. The mechanism diagnosis and treatment are the same as in fracture of the internal epicondyle.

As with fractures of the internal epicondyle epiphyseal separations are frequently associated with posterior dislocation of the elbow. There is occasionally injury to the ulnar nerve.

Treatment of Fractures of the Lower Extremity of the Humerus.—These fractures should be reduced under general anesthesia with the aid of a fluoroscope at the earliest possible moment. Proper reduction is the quickest means of reducing the swelling. The supracondylar and distal humeral fractures and separation of the entire humeral epiphysis simulate posterior dislocation of the elbow as to deformity and may be reduced in a similar manner. Traction is made on the forearm in the partially flexed position and counter pressure is made over the anterior surface of the lower end of the upper fragment. While this combined traction is maintained, the forearm is completely flexed carrying the supinated hand to the shoulder on the same side with the humerus against the side. In this lateral hyperflexed position the arm may be fixed in plaster.

Several turns of plaster of paris bandages are applied (the skin being protected) reaching from the axilla to the condyles. This is allowed to harden on rotation being allowed meanwhile. The hub is then placed so that the humerus lies on the plane of the patient's back. A swathe of appropriate width and long enough to encompass the trunk three times is made of several reduplications of plaster of paris bandage on a strip of lint or sheet wadding. With one end applied to the posterior aspect of the sound axilla the swathe is carried diagonally across the back over the shoulder around the affected forearm and humerus back to the place of starting where it passes over the first end and continues around the front of the chest again to envelop the forearm and arm. The swathe should not be reversed as it comes over the shoulder and diagonally around the wrist and forearm. Turns of plaster bandage can be added to give further stability one or two being carried around the hand as far as the metacarpophalangeal joints for support to the wrist and the prevention of an unsightly droop.

If the forearm is flexed too acutely on the arm the radial pulse will be cut off. It is imperative therefore that the arm be watched carefully for two or three days since slight increased swelling may occur even after reduction and constrict the blood supply. If

such occurs the cast must be removed immediately and the forearm fixed in less acute flexion. In many instances there is a great deal of swelling by the time the patient reaches the surgeon, so that the forearm cannot be fixed acutely enough for the permanent dressing. It is preferable then to flex the arm to about a right angle, place a posterior molded plaster splint from the shoulder to the hand and maintain it in the lateral position by means of a temporary adhesive dressing. In three or four days when the swelling has sufficiently subsided, the flexion of the forearm may be increased and the permanent cast applied as described above.

In some instances fluoroscopic observation will reveal that the reduction can be satisfactorily maintained with the forearm

Fig. 336.—Cross section through trunk and arms at the condylar level. Position A the normal one is retained in the lateral hyperflexed position. Position B is the one assumed where the forearm rests on the chest. E and I represent the external and internal condyles respectively.*

across the chest on an internal right angle splint or in the anterior hyperflexed or Jones position. Such dressings are less cumbersome than the lateral hyperflexed position in a plaster cast. When the lateral hyperflexed position is used the cast may usually be removed in two or three weeks and the arm placed in the Jones position. It is then possible to remove the dressing two or three times a week and exercise the elbow within the limits of pain. At each dressing the forearm may be lowered but the ability to flex the forearm should be maintained. After the fourth week a sling will suffice for support. Complete extension is slow in returning and should not be forced. After six weeks some weight may be carried to aid extension.

In the T or Y fracture traction on the

*Hanson: Fractures of the Humerus, Elbow and Ulna. D. Appleton Century Co., Publishers.

forearm with slight elbow flexion in a Murray-Jones splint as bed treatment may be necessary. A pin or wire through the olecranon may be used at times. In certain refractory cases, open reduction may be necessary. When a fracture of the internal or external condyles cannot be satisfactorily reduced by ordinary means, an open reduction should be done. In recent years some excel-

adults. Restoration of full function may require a year. Uncorrected rotation is a frequent cause of cubitus varus (gunstock deformity). This occurs most frequently in supracondylar fractures. External condylar fractures give better ultimate flexion and extension as a rule than do internal condylar fractures. Internal condylar fractures are difficult to keep reduced and so occasion-

Fig. 337.—Jones position and dressing for many "elbow" fractures. Care should be exercised in this dressing not to rotate the lower fragment.*

lent results have been obtained with the use of the hanging cast for fractures in the lower third of the shaft as well as in the upper two thirds.

In fractures of the capitellum or trochlea, if the fragment is free in the joint it must be removed, as it will not be absorbed. The absence of a radial pulse or the presence of nerve injury usually indicates open operation. [The editor has seen two successful closed reductions of the capitellum (Christopher, F. and Bushnell, L. F.: *J. Bone & Joint Surg.* 17:489, 1935).]

Prognosis.—Function is good after good reduction. The prognosis must be more guarded as to function and deformity in

nally result in non-union. Epicondylar fractures very frequently result in fibrous union but with good function.

Function is to be striven for at the expense of anatomical perfection, therefore, massage and motion must be employed. In fractures through the epiphyseal line, interference with growth may result. This does not apply after the fifteenth to sixteenth year, when growth from the lower epiphysis ceases.

The prognosis in any given case is altered by the occurrence of complications. In supracondylar, diacondylar and epiphyseal

* Roberts and Kelly: *Fractures*. J. B. Lippincott Co. Publishers.

fractures marked swelling and bleb formation may occur. The most common complication is the difficulty in preventing recurrence of the deformity. The median ulnar and more often the musculospiral nerve may be injured. It is important to recognize any such nerve injury before reduction. Definite nerve injury may be an indication for open reduction so that the nerve may be sutured if severed or freed if caught between the fragments. Ischemic muscular atrophy (Volkmann's contracture) is probably due much more to vascular interruption than to impairment of function resultant from faulty reduction. Absence of the radial pulse, pallor and coldness of the hand should be recognized early. Open operation may be required to free the artery from constriction by the bony fragment. The radial pulse will occasionally disappear when the elbow is dressed in acute flexion so that a better reduction must be accomplished or another type of dressing used. Myositis ossificans (ossified hematoma) may occur with most detrimental results on function.

FRACTURES OF THE UPPER EXTREMITY OF THE ULNA

Anatomy.—The olecranon and coronoid processes form a semicircular articulating surface which fits neatly around the trochlea making a hinge joint with the humerus. Thus a force applied through the ulna, as a fall on the elbow, is passed on to the trochlea. However, the trochlea is larger on its medial side and tapers off toward the midline so that a fall on the elbow in the abducted position transmits the force against the side of the capitulum.

Fractures of the olecranon (Fig 338) are the fourth most common fractures involving the elbow joint (13 per cent of the total number). Fracture of the extreme tip or beak occasionally occurs but the usual site of fracture is at the junction of the coronoid process and the olecranon. The epiphyseal line is small and above this site. It enters but little into the elbow joint. The tip of the olecranon before the fourteenth year prior to full development is on a plane anterior to the plane of the shaft of the humerus with the elbow in right angled flexion; hence the infrequency of olecranon fractures in youth.

Etiology.—These fractures are produced by direct violence as by a fall on the elbow or less frequently by muscular action as by

a fall on the semiflexed forearm. Direct violence produces a transverse fracture. Muscular action alone or with direct violence produces a transverse or oblique fracture with or without separation.

Epiphyseal separation is uncommon but is produced by the same mechanism as the fracture. The epiphysis appears during the tenth year and has joined the diaphysis by the seventeenth year.

Diagnosis.—In the absence of separation there is local tenderness, slight swelling and painful and limited extension. When the fracture line enters the joint as it usually does there is joint swelling and a lack of stability of the joint. Wide separation may result from extensive laceration of the triceps expansion. With separation crepitation is absent. The fragment is easily palpated and with the forearm extended it is above its normal level as compared with the opposite side. Fracture of the olecranon may be complicated by anterior dislocation of the radius and ulna or fracture of the internal condyle or the coronoid process.

Treatment.—As a rule there is separation of the fragments and open reduction is necessary. The fragments are approximated with chromic catgut kangaroo tendon or strips of fascia lata. Occasionally a satisfactory reduction may be maintained by extension of the forearm and looping a strip of adhesive tape around the fragment and over the forearm. If there is no separation of the fragments an internal right angle splint will suffice.

Motion is cautiously begun in two weeks. The splint is removed after union has occurred usually in five or six weeks.

The prognosis is good if approximation of the fragment has been secured. Even if separation is present fibrous union results and if the stability of the joint is not affected by the widened hinge function will be good and the union strong. Stimson mentions the fact that ankylosis has followed in a certain number of cases. The fact that this fracture enters the joint jeopardizes ultimate function especially in adults.

Fractures of the coronoid process are usually associated with posterior dislocation of the elbow (Fig 338).

Etiology.—The usual cause is a fall on the arm in flexion which results in pos-

terior dislocation of the elbow and an incidental fracture of the coronoid process. Writers have reported this fracture as being unaccompanied by posterior dislocation but this is unlikely. If a sufficiently careful history is taken in fracture cases most of the patients will be found to have had a partial dislocation that snapped back after the fracture occurred or had been reduced previous to the x-ray diagnosis. Some authors mention muscular action but this seems unlikely as many of the fractures are of the tip of the process where the brachialis anticus muscle is attached at its base. Direct violence resulting in a crush fracture may break the coronoid process.

hence union is the usual result. In the roentgenogram the view must be a direct lateral one and unless the picture is clear the fragment may not be detected.

Treatment—The hyperflexed or Jones position maintained for two or three weeks followed by the use of an internal right angle splint or a Bolles splint is the most satisfactory treatment. Massage and slight motion (from 10 to 15 degrees) should be started after the tenth day. All splints should be removed in five or six weeks and a sling used intermittently for fatigue. If there is no displacement the arm may be dressed from the beginning in the right angled position.

Fig. 338.—Fracture of olecranon and coronoid processes of ulna and high fracture of neck of radius. Boy, age sixteen years. Fell 20 feet striking on elbow.

Diagnosis—Definite diagnosis without the help of a roentgenogram is virtually impossible except in cases in which a large fragment exists in a thin person who is seen before swelling occurs. Clinically one is led to suspect a coronoid fracture if a case of posterior dislocation of both bones at the elbow tends to recur easily. Tenderness and possibly a fullness in the antecubital fossa to the inner side of the biceps tendon may be found. While displacement is rare the fragments usually being held as on a hinge by the periosteum, the capsular ligament and the expansion of the brachialis attachment.

Prognosis—Results are extremely favorable in growing children as are those in all joints. A more guarded prognosis must be given in older patients especially those with evidence of osteoarthritic changes. Oscification of the hematoma which develops in the region of the fracture may cause complete ankylosis.

Fractures of the Upper End of the Radius—The nucleus of the upper epiphysis of the radius appears about the fifth year and unites with the diaphysis during the six-

* *Fractures of the Humerus, Radius and Ulna*. D. Appleton Century Co. Publishers.

teenth year. The epiphysis includes only the upper portion of the head, the lower part and the neck being ossified from the shaft. The head is entirely intra-articular and has no ligamentous attachments.

The head of the radius articulates with the capitellum and is palpable just below the external condyle. It is most prominent in extreme pronation of the forearm. The head and the upper part of the neck are intra-articular, made so by the orbicular ligament which attaches only to the inner side of the neck.

Fractures of the head of the radius are second in number only to supracondylar fractures in statistics on fractures at the elbow joint.

Etiology.—The fracture is usually produced by a fall on the pronated hand with the forearm extended. The trauma is thus transmitted to the head of the radius as it is driven against the capitellum. Direct violence is another cause of this fracture.

Diagnosis.—The entire head may be crushed or broken off or the fracture may be simple, stellate or comminuted in almost any manner. Displacement is usually not great. There is pain, increased on motion with tenderness over the head of the radius. Crepitus is rare. If the fragment is displaced inward it completely limits flexion; if outward, it is over the external condyle and easily palpable. When there is no displacement a roentgenogram is usually required to make the diagnosis. In patients between the ages of five and seventeen this may be a separation of the epiphysis. The etiology and symptoms are the same as in cases of fracture.

Treatment.—In fractures without displacement the limb is dressed preferably in mid-pronation on an internal right angled splint. After ten days, gentle motion is begun. Fixation is maintained for from three to six weeks, depending on the age of the patient. If the fragments are free in the joint, they should be removed in order to obtain good function.

Prognosis.—If the fragments are impacted or if the longitudinal break into the neck has periosteal attachment, union will occur. If there is wide separation of the fragments,

the results are better when treated by operation (Speed, Cotton, Stimson, *et al.*). The fracture is occasionally associated with fracture of the external condyle of the humerus, dislocation of the radius, dislocation of both bones, fractures of the coronoid process and fractures of the shaft of the ulna.

Fractures of the neck of the radius are only about one fourth as common as those of the head. About half of these occur in

Fig. 339.—Fracture of the upper end of the shaft of the ulna together with anterior dislocation of the head of the radius.*

patients under twenty years of age (Fig. 338).

Etiology.—This fracture, like that of the head of the radius, is usually caused by a fall on the outstretched hand, with the forearm extended and in pronation. Extreme abduction of the forearm at the elbow is said to cause it.

Diagnosis.—In complete fracture the upper fragment is turned outward by action of

* Eliason: Fractures of the Humerus, Radius and Ulna. D. Appleton-Century Co. Publishers.

the supinator brevis. If the fracture is oblique it is partially extracapsular. An incomplete fracture occurs in children. Localized pain, tenderness, swelling and possibly deformity and crepitus are noted. The head does not rotate with the shaft unless the fracture is impacted or incomplete. Supination is limited and painful.

Treatment—When reduction under the fluoroscope is unsuccessful, excision should be performed. If the fracture can be reduced it is best dressed over mobilized plaster splints in full supination and with 90 degree flexion. Massage is begun on the tenth day and slight motion in two weeks. The splints are worn for from four to six weeks.

The prognosis in uncomplicated cases is good although there may be slight limitation in rotation. The fracture may be associated with other fractures in this region especially of the olecranon, coronoid process or shaft of the ulna.

General Considerations of Fractures in and around the Elbow Joint (1) Early reduction is usually the easiest reduction. (2) Loss of flexion is more crippling than loss of extension. (3) Loss of pronation can be compensated by an abduction of the limb; loss of supination has no compensatory factor. (4) Increased carrying angle is often followed by ulnar neuritis. (5) The prognosis should be guarded when the fracture involves the joint for the results in the form of traumatic arthritis often take years to develop. (6) Traumatic myositis ossificans or ossified hematoma occasionally occurs within the brachialis anticus muscle. (7) A loose fragment in the joint is a bad tenant.

FRACTURES OF THE RADIUS AND ULNA

FRACTURES OF THE DISTAL END OF THE RADIUS (COLLES' FRACTURE)

Etiology—The cause of a Colles' fracture is almost always a fall on the outstretched hand. The type of fracture and its bony deformity depend upon the force of the fall and the position of the hand at the time of impact.

Pathology—The injury involves the surrounding soft parts as well as bone. The distal fragment usually is driven dorsalward along with the hand and carpus so that the structures in the volar carpal canal (the flexor tendons and median nerve) are drawn against the end of the proximal bone fragment (Fig. 341). Injury to the extensor pollicis longus tendon at the fracture level followed by subsequent spontaneous rupture occasionally occurs. The radial or ulnar arteries may be compressed. The pulse and the nerve and when possible tendon function always should be tested before and after reduction of the fracture.

The triangular fibrocartilage may be torn or avulsed. If intact, abnormal tension is put upon it especially in positions of full rotation by slight residual shortening of the radius (Fig. 341). Such shortening also deranges the mechanics of the inferior radio-ulnar joint. The net result may be a painful wrist necessitating subperiosteal resection of the ulnar head for its relief. Consequently for prevention of such a late complication it is of utmost importance that the radial length be regained and maintained until bony healing occurs. Associated fractures of the ulnar styloid occur in more than 50 per cent of all Colles' lesions. They require no attention despite the fact that bony union is rare. Not uncommonly there may be an associated fracture of the radial head, carpal scaphoid, ulnar head or surgical neck of the humerus. The therapy necessary for such additional lesions may complicate or be complicated by the treatment of the Colles' fracture.

Diagnosis—The pathologic anatomy of

lows a fairly consistent pattern upon which the clinical diagnosis may be based. For its full comprehension four anatomic features of the normal wrist must be kept in mind (Fig 340).

(1) The radial styloid is at a level about 1 cm distal to that of the ulna making the plane of the joint such that (2) the long axis of the hand deviates ulnarwards about 10 degrees from the midline. (3) The long axis of the third metacarpal meets that of the forearm at the level of the wrist joint. (4) The dorsal surface of the wrist is flat while the ventral surface is curved concave volarwards.

across the dorsum of the radius. (3) *Radial tilt or deviation* of the distal fragment which deranges the styloid relationships and reduces or reverses the normal ulnar deviation of the hand. (4) *Radial shift or displacement* of the distal fragment which shifts the long axis of the third metacarpal radialwards and results in undue prominence of the ulnar head. (5) *Impaction* of the two fragments or *overriding* which produces shortening of the radius as estimated by the styloid levels.

A reverse Colles fracture is a relatively uncommon lesion characterized by volar displacement or angulation of the distal

Fig 340—Diagram showing the anatomic features of the normal wrist

A Colles fracture may be without displacement or it may be characterized by one or all or any combination of the following deformities each of which affects the anatomic features in a way that can be recognized clinically by inspection or palpation (Fig 341).

(1) *Dorsal tilt or angulation* of the distal fragment which if small reduces and if large reverses the volar curve. (2) *Dorsal shift or displacement* of the distal fragment which deranges the volar curve and produces a palpable bony ridge transversely

fragment so that the normal volar curve becomes accentuated when compared to that of the normal wrist. Some rotatory deformity frequently is present in all Colles fractures but seldom is clinically evident. In addition to the existing anatomic derangement diagnostic evidence is almost always present in the form of swelling which originates on the dorsal surface and extends circumferentially. Direct and indirect tenderness at the fracture site, pain aggravated by any motion of the wrist, and frequently volar ecchymosis.

Treatment—Treatment should be preceded by first aid measures consisting of adequate sedation and the application of an emergency board splint and sling. Reduction is most easily accomplished under light general anesthesia. If this is contraindicated, local injection of 15 to 30 cc of 1 per cent novocain may be used with satisfactory results in the first twelve hours during which the fracture hematoma remains in a fluid state. Hematoma blood should be withdrawn into the syringe before novocain is injected. After twelve hours has passed local anesthesia becomes progressively less satisfac-

of reduction is by determination of the re-establishment of the normal anatomic characteristics of the wrist (Fig 340). Fluoroscopic facilities are of great value in the confirmation of reduction but their consistent use as an aid in reduction is unnecessary and unwise.

Maintenance of reduction is best accomplished by plaster splints which may be molded to both dorsal and volar surfaces of the forearm or carried around the flexed elbow with the forearm in mid rotation in the form of a sugar tong, so as to control excessive rotary motion. A circular plaster

Fig 341

Fig 342

Fig 341.—Diagram showing the pathologic findings in a fracture of the distal end of the radius (Colles' fracture)
Fig 342.—Lateral aspect of same fracture

tory. If the ulnar styloid is fractured, injection of the novocain into this region also is indicated.

The *reduction maneuvers* depend upon the bony deformities present. Primary distal impaction should precede any attempt at reduction of an impacted fracture. All manipulations are facilitated by preliminary traction sufficient to relax the existing muscle spasm. Angulations should be corrected and displacements reduced one at a time by manipulation of the distal fragment with one hand while the proximal fragment is stabilized with the other. Clinical confirmation

of reduction is by determination of the re-establishment of the normal anatomic characteristics of the wrist (Fig 340). Fluoroscopic facilities are of great value in the confirmation of reduction but their consistent use as an aid in reduction is unnecessary and unwise.

Maintenance of reduction is best accomplished by plaster splints which may be molded to both dorsal and volar surfaces of the forearm or carried around the flexed elbow with the forearm in mid rotation in the form of a sugar tong, so as to control excessive rotary motion. A circular plaster

sion of the dorsal tendons, ligaments and capsule, a recurrence of the deformity. In the same way, ulnar deviation usually is required for maintenance of length and correction of radialwards deformities. A reverse Colles fracture requires hyperextension. The proper amount of any such position is

cases (Fig 341). When moderate in amount, reduction may be maintained by immobilization in a position of wrist flexion. The duration of immobilization required varies directly with the degree of comminution. Extensively comminuted fractures tend to collapse and shorten inside any type of ex-

Double Pins Incorporated in Circular Plaster

Multiple pins fixed at A by mechanical apparatus

Internal fixation by plate and screws

Fig 343—Methods of skeletal fixation in fractures of both bones of the forearm

the least amount necessary for the maintenance of reduction and can be determined only by the operator. Whenever such abnormal positions are found to be unnecessary, the hand should be placed in the grasp position of maximum function, with the wrist extended.

Dorsal comminution is present in many

internal splint and can be controlled only by the additional use of two Kirschner wires, one through the olecranon and the other through one or several metacarpals (Fig. 343). During reduction, normal length may be obtained by distraction of the two wires by assistants, and following reduction, maintenance of length may be accomplished by

incorporating both wires into the immobilizing plaster so that shortening cannot occur.

After Care—Adequate after care demands the following precautions:

1. Frequent inspection of the circulatory status of the hand is necessary, especially during the first week. As swelling increases the splints should be rebanded less tightly. Later as it subsides they should be tightened progressively. A comminuted lesion requiring the use of wire traction necessitates the application of a circular plaster splint; therefore the patient should be hospitalized until the circulatory status of the part returns to within the limits of safety.

2. Early and constant light use and exercise of the fingers must be insisted upon. When necessary resumption of finger function may be initiated by a set of simple exercises such as squeezing a rubber ball or sponge or opposing finger tips to thumb.

3. Maintenance of shoulder mobility should be given particular attention since the shoulder may become stiffened and painful from disuse, especially in a person past middle age.

4. Roentgen examinations are required for confirmation of reduction followed by subsequent films to determine that the position is maintained. A ray is of little or no value in estimating the time for removal of splints since visible callus at the fracture site is small in amount and evidence of bony union by x ray is not present until weeks or months after clinical union has occurred.

The duration of immobilization depends upon the type of fracture and the amount of comminution. Undisplaced fractures and impaled lesions not requiring reduction are splinted for rest, comfort and protection rather than maintenance of position. Therefore splints should be removed for warm soaks and active wrist exercises as soon as symptoms will permit (usually within a week) and should be discarded within about two weeks or slightly longer. The average Colles fracture requires two to four weeks of splinting following reduction and the duration must be determined by the operator on a basis of the stability of the fracture at the time of reduction. The more comminuted the fracture the longer it should remain immobilized. Badly comminuted

fractures, especially those necessitating the use of wire traction, require a minimum of six weeks of immobilization. Under ordinary circumstances splints should be discarded gradually as progressive healing lessens the need for external support rather than suddenly. A leather or elastic wristlet minimizes the pain and weakness which commonly follow the final removal of all external splints.

It occasionally is unwise to aim for anatomic restoration of the bone fragments. This is particularly true in the case of elderly arthritic patients in whom the institution of immobilization sufficient to maintain the reduction of a comminuted Colles fracture may result in a permanently stiffened and painful wrist regardless of the anatomic perfection evidenced roentgenographically. Gross bony deformity does not always result in pain or disability, whereas protracted immobilization of an arthritic wrist of an elderly person is very apt to do so. In selected cases the patient should be warned of residual deformity; the wrist should be splinted for rest and comfort without any reduction and an effort should be made to maintain function rather than position. In the early institution of warm soaks, active exercises and use. The usual result will be a deformed but useful and reasonably comfortable wrist.

EPiphyseal INJURIES AT THE DISTAL RADIAL EPYPHYSIS

Epiphyseal injuries are more common at the distal end of the radius than in any other location of the body. Subsequent growth disturbance is to be expected in less than 5 per cent of such injuries. Sprain of the wrist is almost a nonentity in children and less so that appear to be a sprain almost always are undisplaced epiphyseal injuries in which in spite of completely negative x ray evidence the risk of subsequent growth derangement is just as great as if the epiphyses were grossly displaced. The diagnosis can not be made by x ray but becomes reasonably certain if circumferential tenderness limited to the epiphyseal area persists for more than a week. The active treatment of such lesions requires nothing more than a temporary splint for comfort and protection. If it can be accomplished without force a

grossly displaced radial epiphysis deserves reduction followed by several weeks of immobilization. If reduction cannot be accomplished without undue force it is wise to immobilize the lesion in an incompletely reduced position. Forceful or repeated attempts at reduction strongly predispose to subsequent growth disturbance and open reduction almost insures it whereas most mild displacement deformities tend to be corrected by growth. The prognosis should be guarded in all epiphyseal injuries no matter how innocuous they seem at the time of treatment.

FRACTURES OF BOTH BONES OF THE FOREARM

Anatomy—The intricate muscular innervation of the forearm must be kept in mind when dealing with fractures of both radius and ulna. It is the most important single factor to be overcome in the reduction and the subsequent maintenance of position of the fracture.

1 The radius is curved concave volarwards. This curve is essential to pronation and supination during which it is necessary for the radius to roll circumferentially around the long axis of the ulna.

2 The shafts of the radius and ulna are connected by the interosseous membrane which in fracture is seldom torn enough for the two bones to separate or override to any marked degree.

3 The shafts are most widely separated in the position of full supination. In full pronation they are crossed scissors like in their middle thirds.

4 When the continuity of the radius is broken distal to the insertion of the pronator teres both fragments are pulled volarwards and towards the ulna the proximal by the teres and the distal by the pronator quadratus. Unopposed pull of the quadratus also tends to pronate the distal fragment whereas the teres is neutralized by the supinators attached to the proximal fragment.

5 When the radius is fractured proximal to the insertion of the teres the distal fragment is pronated and pulled ulnarwards by unopposed action of both pronators. The proximal fragment is flexed and supinated by the unopposed action of the biceps and supinator brevis.

6 The integrity of the inferior radioulnar joint is in part dependent upon the relative lengths of the two bones.

Pathology—The pathologic and therapeutic importance of these anatomic features manifests itself in the following ways:

1 Any gross angulation of the radius and even a slight one if against the normal curve results in some limitation of motion. Consequently the correction of angular deformities and especially those with apex volarwards is of utmost importance.

2 Fibrosis and contracture of the interosseous membrane tend to pull the fractured shafts closer to one another. Limitation of rotation results whenever this is allowed to occur. Occasionally cross union may take place between the two fractures.

3 The optimum position for immobilization is that which maintains an adequate width of interosseous space i.e. mid position to full supination never pronation.

4 When the ends of both fragments are pulled volarwards by the pronators full supination tends to accentuate the deformity. Under these circumstances the optimum position for immobilization is the mid position.

5 When the proximal fragment is flexed and supinated the long and controllable distal fragment must be realigned to suit it because the position of the proximal fragment cannot be controlled by any external splint. This requires that both reduction and immobilization be done with the elbow flexed to a right angle and supinated fully.

6 Relative shortening of the radius produces pain in the wrist by the same mechanism as described under the pathology of a Colles fracture. It is important therefore that the relative lengths of the two bones be maintained.

Diagnosis—The diagnosis usually is obvious. Extensive damage limited to the sub-fascial region predisposes to circulatory embarrassment and care must be taken not only to ascertain that vascular function is intact but also to make sure that any constricting dressings applied do not jeopardize it. Interposition of muscle or fascia between the bone ends is not uncommon and should be ruled out before reduction is attempted by gently demonstrating the presence of crepitus. Nerve injury is not common but

its absence should always be determined. Fragments with marked displacement may pierce and become caught in the deep fascia and may be identified by the presence of an adherent dimpling of the skin at the point where the fascia is impaled.

Treatment—In adults the muscles are strong and the force required to break the bones is great. Comminution is common. Because of these factors reduction and maintenance of position is extremely difficult by conservative measures. When manipulative reduction has to be done it should not be attempted except under general anesthesia. Manual traction and countertraction until all muscles are relaxed and length has been regained should precede any attempt to reappose the ends of the broken bones. Even after reduction has been accomplished in many cases there is a tendency for the fragments to angulate towards each other so that the risk of cross union becomes significant. This tendency can be overcome best by maneuvering the forearm into various positions of rotation until that which produces the optimum width of the interosseous space is found. Immobilization which of necessity must include both wrist and elbow should be instituted in this optimum position. Anatomic reposition of both fragments is important and the healing time is protracted at best. Because of the diverse muscular forces to which the fragments are subjected maintenance of position by plaster alone is not only very difficult but also inefficient and often inadequate. The use of skeletal traction in the form of Kirschner wires incorporated into the plaster serves to maintain normal length but has no control over existing rotary or displacement deformities (Fig. 343). The technical difficulties and potential complications embodied in the use of the various multiple pin fixation devices gives this method of treatment (Fig. 343) all the disadvantages and none of the advantages of open reduction except when used by an expert under ideal conditions. The treatment of choice when possible is early open reduction rigid internal fixation a minimum of postoperative external support and early resumption of use.

In children fractures of the forearm are commonly incomplete the so-called *green stick* or *buckle fracture*. When such an an-

gular lesion slightly increases the normal curve of the radius no reduction is necessary. All other angulations warrant correction. Complete or even adequate reduction can be obtained and maintained only by reversing the angulation until both cortices are broken. In completing such a fracture care is required lest displacement of the fragments occur.

Complete fractures in children are subject to the same muscular forces as those in adults. Less accurate reduction is sufficient to insure a good result however especially in younger children because in inverse proportion to the age of the patient the compensatory growth of the bone has the power to correct almost all except rotary and gross angular deformities. While anatomic reposition of fragments is optimum in the reduction of a forearm fracture in the child the minimum requirements for adequate reduction demand only eradication of rotary deformity and reestablishment of bony contact and alignment. Before end to end contact can be obtained in overriding fractures it often is necessary to angulate the fragments sharply reappose the bone ends in the angulated position and then straighten out the angulation in the manner of a carpenter's toggle joint.

Immobilization is best accomplished by plaster splints which must include both wrist and elbow. The same rules for position during immobilization apply regardless of whether both bones or only the radius is fractured. Unlike the same fractures in the adult healing by bony union is reasonably certain within four to six weeks. Refracture is common however unless some form of external support is retained for a minimum of eight weeks especially in fractures of the proximal half of the bones.

FRACTURES OF THE SHAFT OF THE RADIUS

Fractures of the radial shaft will out an associated fracture of the shaft of the ulna are under ordinary circumstance subject to the same anatomic pathologic and therapeutic considerations as fractures of both bones. Frequently the lesion is accompanied by a fracture of the ulnar styloid. A not uncommon lesion in the adult is a transverse or short oblique fracture through the middle or lower third of the bone. While this

lesion looks rather innocuous roentgenographically and while it is found to be easily reducible (it is seldom displaced more than a small amount, with the proximal end of the distal fragment pulled towards the ulna by the pronator quadratus) it is also found that it is virtually impossible to maintain adequate reduction delayed union (often as much as four to six months) being common. Interposition of the fibers of the pronator teres insertion is common and whenever it can be done safely open reduction is strongly indicated.

FRACTURES OF THE SHAFT OF THE ULNA

Fractures of the ulnar shaft uncomplicated by a fracture of the radius occur from direct violence. When situated in the proximal half of the bone and especially if characterized by angulation pointing volar wards or laterally it should be assumed until proved otherwise that there is an accompanying rupture of the orbicular ligament allowing an anterior dislocation of the radial head. Displacement is usually minimal in amount and the attachments of the interosseous membrane seldom allow any significant angulation except in those accompanied by dislocation of the radial head. The treatment of uncomplicated ulnar fractures requires nothing more than immobilization for three to five weeks by molded plaster with the forearm in mid rotation.

HARRISON L. McLAUGHLIN

FRACTURES OF THE CARPAL BONES

Anatomy.—The eight bones of the carpus tightly packed together bound by dorsal volar and interosseous ligaments to each other to the radius and to the metacarpus provide the basis for the support of the hand. These bones clinically and anatomically may be divided into two rows. The first or proximal row is comprised of the os naviculare and os lunatum and articulates proximally with the radius and distally with the second row. The second row includes the pisiform os triquetrum and os hamatum on the ulnar side, the os capitatum (the key-stone central bone) and the os multangulum minus and majus (supporting the thumb) on the radial side of the wrist. True synovial

lined joints exist irregularly between them much of the surface of the bones is cartilaginous. The attachments of the ligaments occur on rough bony areas devoid of cartilage through which a rather scant blood supply penetrates the various bodies. By arrangement of coordinated movements of the intercarpal joints the normal adult wrist is mobile yet strong partly supported by the numerous tendons passing on both dorsal and volar surfaces. It presents a range of motion approximating dorsal flexion of 45 degrees volar flexion of from 60 to 70 ulnar flexion of 10 and radial flexion of 20 degrees. During these movements the axis and position of the two bones of the proximal row change yet the bones remain bound to each other to the radius and to the distal row of carpal bones but on account of this mobility and axis shifting they are the seat of most of the fractures and dislocations of the carpal area.

Carpal fractures represent about 15 per cent of all fractures of the skeleton with a higher proportion in military service they may seriously influence the use of the hand and if imperfectly healed result in diminution of the patient's wage-earning power with functional loss. Fractures of the navicular dislocation of the lunate and dislocations around the lunate bone is the order of occurrence. The latter group presents a severe type of injury often accompanied by fractures of the navicular radius and ulna or other carpal bones sometimes leaving the lunate in normal relationship with the radius. Fractures and extremely uncommon dislocations of the remaining carpal bones may occur. Unfortunately the greater mobility of and frequency of injury in the two bones of the proximal row are coupled with their relatively scant and precarious blood supply obtained largely through ligamentous attachment. Fractures and dislocations in this row therefore may be expected to require prolonged immobilization in order to insure the restoration of the blood supply maintenance of vitality healing and restoration of function.

Etiology.—The two mechanisms causing these lesions are direct and indirect violence, the former acting less often than the latter. Direct violence from a blow on the wrist by a stick or crushing mass may cause a lesion

regardless of the position or exposure of the hand at the instant of application and may consequently lead to open wounds involving tendons, nerves and blood vessels. The most common carpal lesion results from indirect violence usually received in falls on the hand, in back-fire injuries from cranking a motor or crush violence. The mechanism of fracture is similar to that of Colles' fracture, which may accompany it; each lesion must be studied in the two view roentgenogram to eliminate the other force transmitted through the fingers when a person falls on his hand is carried to the wrist via the metacarpal bones and meets there the force of

bowstring of the transverse carpal ligament preventing release from pressure. A similar mechanism, depending on the degree of radial, ulnar, dorsal or volar flexion in which the hand and wrist meet the emergency, results in the other carpal lesions; the lunate bone may become the central point of the application of the violence, or the ligaments binding it to the capitate or wrist may be torn off to permit it to be forced out of joint, just like a pit squeezed out of a cherry. The surrounding bones may be pushed away from it into dislocations, either dorsal or volar, carrying the navicular bone *en masse* with them. Often the navicular bone, on ac-

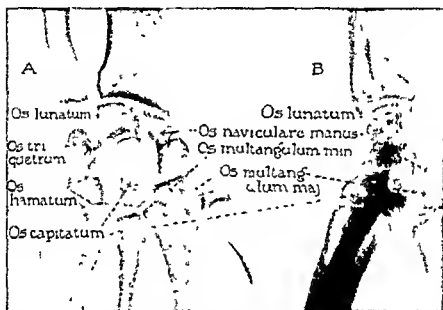

Fig 314—Arrow points to a typical transverse fracture of the navicular with little separation of fragments. In the posteroanterior view (A), no abnormal over-riding of the shadow of the carpal bones is seen. Study of the lateral view (B) demonstrates the outlines of the lunate, navicular and capitate in normal position without dislocation.

the superimposed falling body transmitted down the forearm in the person's attempt to catch himself and save a more serious injury. The violence may act by crushing the carpal bones, nearly always those of the proximal row, against the radius, or by a combination of compression and an overextension or flexion of the wrist may crack across the navicular, which is compelled to accommodate itself by changed axis and rotation to the exaggerated position while under powerful compression. This effort may cause the bone to be caught between two forces and cracked like a nut contained in an arch-like arrangement, with the strong

count of the position of the hand and wrist. is broken across, the proximal fragment bound by ligaments to the lunate remaining with it, while the distal fragment goes along with the rest of the carpal bones into dislocation around the lunate. These are the complicated perilunar dislocations, for more detailed description and illustration of which one is referred to the writer's monograph on injuries of the carpus.

carpi radialis which may become the seat of traumatic synovitis. Most of the fractures are intra articular the synovial fluid becomes blood tinged and swelling and edema of the wrist region and its tendons and coverings follow. Interference with function is mainly a reaction to the pain of movement or the effect of grasping.

The bone involved taking the navicular as the most common may be cracked across the middle or near the proximal third may be crushed rarely comminuted or may sustain a fracture of its tuberosity. Displacement of any bone fragment is not great although dislocation combined with lesions of neighboring carpal forearm or metacarpal bones may be found. The tearing away of the ligaments may avulse small chip-like fragments from the bone surface but its most untoward result is the interference with the blood supply of the bone. Unless there is immediate immobilization this deprivation of nutrition may lead to aseptic necrosis of the part of the bone involved (usually the proximal fragment but often both fragments) although the distal portion of the navicular bone receives an accessory source of vascularization through its tubercle which has completely extra articular with excellent ligamentous attachment. At first the crack into the bone may be so faint that it is overlooked in the x-ray examination made immediately but as loss of nourishment and necrosis progress the fracture plain develops and becomes more apparent in the roentgenogram and the density of the bone as a whole when viewed in the film appears greater than that of the surrounding bones which rapidly lose shining casting calcium salts as a result of atrophy of disuse. In some instances of Sudeck's atrophy the density contrast may become astonishing in one week. Additional changes consist of extension of bone necrosis in the body of the bone and efforts at absorption and replacement which are exceedingly slow with ligamentous thickening and new bone reaction on adjacent surfaces of the radius. Ultimately the cancellous portion of the bone may die and an absorptive process may lead to cavity formation and fragmentation of the bone the cartilaginous covering surviving the longest. In some instances the history of the primary trauma being forgot-

ten a condition of traumatic osteomalacia is thought to be present. When this concerns the lunate bone original fracture may be denied the condition being called Kienbock's disease a term introduced by the writer some years after Kienbock's original description. When the condition is found in the navicular bone it is often called Preiser's disease. The further the disintegration of the bone advances usually the greater the pain and stiffness in the carpus although some persons reach a resting stage from five to ten years after fracture when the distress may decrease somewhat.

Symptomatology—The symptoms of carpal fracture or fracture dislocation are primarily pain and partial interference with the function of the wrist and hand but not complete loss by any means. A worker may fail to report a wrist injury which has caused fracture. He may consider the lesion a sprain and be confirmed in this opinion by a physician who fails to make a careful roentgenologic examination. Local tenderness over the wrist bone involved curtailment of the normal range of wrist joint excursions as compared with that of the normal hand swelling and pain on pressure in the tubercle (which may be obliterated by the swelling) when the navicular is involved or in the wrist bone after percussion of the head of the middle metatarsal bone complete the clinical findings. The roentgenogram is also lately necessary to complete the diagnosis. The film should show the two wrists taken at the same angle in two axes. The character of the fracture as a faint plane across the bone's narrow axis a crushing or a fracture of the tuberosity of the navicular for example then becomes apparent. Definite roentgen ray findings in fracture of the lunate bone may be quite delayed. A careful study of the roentgenograms to determine the anatomical position of the carpal bones is required to eliminate dislocation which may be present.

Treatment of carpal fractures and dislocations depends on the bone involved and the complexity of the lesion. For fractures of the tuberosity of the navicular bone no splint or immobilization of the wrist is required. Slightly guarded use not causing pain will result in bony union. For all other uncomplicated fractures of the navicular,

lunate and other carpal bones immediate and prolonged immobilization is necessary. With the hand held straight the hand, wrist and forearm should be put in a plaster of paris encasement which is light, meagerly padded and close fitting and encloses the thumb in a position of slight abduction extending to the base of the fingers and at least two thirds of the way up the forearm. For navicular and lunate fractures this immobilization must last for eight weeks and then roentgenologic examination must convince the surgeon that bony union has been secured; otherwise the dressing must be re-applied and an examination made after six or eight weeks of further immobilization to determine the character of the union. Surgical removal of one or both fragments of the navicular bone immediately after the fracture has occurred should never be performed. Immobilization of fractures of the distal row may require only five to six weeks.

Fracture dislocations call for reduction under anesthesia accomplished by traction on the fingers, hyperextension and local pressure on the displaced lunate or other bones to push them back into place. This is followed by plaster immobilization for from four to twelve weeks depending on the bone involved.

Old fractures or fracture dislocations may be treated by surgical means. When a lunate bone has been dislocated out of position for more than a week it usually has undergone considerable change in nutrition or has suffered fracture not visible in the roentgenogram. It may be reduced by manipulation or open operation but the reduction is no guarantee that the bone will return to full health. Progress of bone changes must be studied every few months by x-ray plates. Many old dislocations do best with excision of the fractured or displaced bones, each case studied on its own merits.

Ancient fractures of the navicular bone without fragment dislocation may be treated in several ways, the most tedious but often most successful being a return to immobilization in plaster. The length of time required to obtain union may be from three to ten months but may be hoped for up to one year. If economic conditions do not warrant wearing a plaster dressing this length of time, shorter methods can be adopted such

as excision of the whole bone leaving no fragments behind and causing no injuries to neighboring bones by rough handling. Use is started as soon as the soft parts heal. This treatment is advisable for Kienbock's disease of the lunate bone but the condition may yield to a trial of prolonged immobilization with roentgenographic control.

Other operative procedures include efforts to secure bony union by a direct attack on the bone itself. The best of these is simple boring through the fragment with a $\frac{5}{16}$ inch drill or by implanting in a hole thus made a small transplant of autogenous bone followed by three months immobilization in plaster. For non union of the fractures of the distal row sometimes accompanied by subluxation or arthrodosis of the adjacent carpal joints gives relief from pain and good function. The radiocarpal joint should never thus be stiffened. Excellent functional results have been obtained by these methods.

The prognosis of carpal fractures depends on their early recognition and treatment by immobilization. The prognosis of fracture-dislocations is grave; their recognition is difficult and their treatment usually requires expert advice. The ancient cases can be much improved by a well planned and executed surgical attack.

FRACTURES OF THE METACARPALS AND PHALANGES

Fractures of the metacarpals and phalanges are the most common fractures in the skeletal system. Their importance to any one who lives by handicraft should not be underestimated. The distal portion of the hand is most liable to injury. Our study of 1323 fractures involving the bones of the hand showed the following distributions:

	Cases	Per Cent
Distal phalanx	800	60
Middle phalanx	221	1
Proximal phalanx	189	14
Metacarpals	91	7

Movements of the Fingers—Two separate series of movements occur in relation to the articulations of the fingers: flexion and extension (at the metacarpophalangeal and interphalangeal joints), a lateral abduction and adduction (only at the metacarpophalangeal joints). The movements and the muscles concerned are given in the following tables:

Flexion

Flexor digitorum sublimis
Flexor digitorum profundus
Lumbricales } Acting on the metacarpophalangeal and
Interossei } articulations
Flexor digiti quinti brevis

Adduction

Flexor brevis and Opponens digiti quinti } From the medial side of the
Dorsal interossei } From the middle line of the middle finger

Flexion is more powerful and complete than extension of the fingers. The flexor digitorum profundus alone acts on the terminal phalanges; the flexor sublimis and the flexor profundus together flex the proximal interphalangeal joint; flexion of the metacarpophalangeal joint is affected by these muscles as aided by the interossei, lumbricales and flexor digiti quinti brevis. Extension of the phalanges is brought about by the united action of the extensors of the digits, the interossei and lumbricales. Extension of the fingers at the metacarpophalangeal joints is produced solely by the long extensor muscles. Separate extension of the index finger only is possible; the three inner fingers can be extended together completely only because of the connecting bands joining the extensor tendons on the back of the hand.

The arrangement of the interosseal and lumbrical muscles and the insertions of the flexor and extensor tendons are illustrated in figure 315.

Fractures of the Distal Phalanx—The terminal phalanx is attached only at its proximal end to the middle phalanx. Its

distal portion is free and not subject to the action of either the intrinsic or extrinsic muscles. It is here that considerable crushing of fragments may occur with but slight displacement. Fractures involving the proximal portion of the terminal phalanx are subject to the action of the flexor profundus tendon and the extensor communis tendon. A fracture here may develop a varying degree of dorsal displacement of the proximal fragment. Occasionally the entire proximal fragment may be avulsed. In tendon avulsions the flexor or extensor tendon may take with it its bony insertion. The treatment of fractures of the distal portion usually requires simple immobilization. Occasionally molding of the crushed fragments may be required. Fractures of the proximal portion require such immobilization as will approximate the fragments. Complete evulsion of the entire proximal fragment usually requires open reduction. Dorsal displacement

Extension

Extensor digitorum communis
Extensor indicis proprius
Extensor digiti quinti proprius
Lumbricales } Acting on the interphalangeal articulations

Adduction

Volar interossei—To the middle line of the middle finger

of the proximal fragment requires hyperextension and flexor tendon avulsion requires hyperflexion. Usually immobilization for one week is sufficient in crushing injuries of the distal portion. In avulsions of tendons and fractures near the proximal end an immobilization of two weeks is necessary.

Fractures of the middle phalanx owe their displacements to the action of the flexor digitorum sublimis. This muscle ends in a tendon which divides into two portions. They insert one on each side of the middle phalanx at approximately the mid portion. The deformity produced will depend on the location of the fracture site. If this site is distal to the insertion of the tendon, there occurs flexion of the proximal fragment and dorsal displacement of the distal fragment. When the fracture site is proximal to the tendon insertion, there is produced flexion

displacement of the distal fragment with the proximal fragment in an extended position Figure 345 demonstrates these points

be obtained by bringing the distal fragment into line by the use of a curved splint restoring the fragments to the natural arc

Fig 345—Fractures of the metacarpals and the phalanges

Failure to take into account these two types of displacement of fragments will result in a failure to correct the deformity

Fig 346—*a* Volar spur resulting from fixation of fractured middle phalanx on a straight splint *b* restoration of normal curvature on a curved splint

There results most commonly a palmar projecting spur which interferes with flexion of the distal phalanx (Fig 346)

In the second type adequate fixation can

which was present before the fracture took place

Fractures of the Proximal Phalanx—
The resulting deformity when fracture of the proximal phalanx occurs is fairly constant regardless of the site of fracture (Fig 345). As can be seen in the accompanying illustration palmar displacement of the proximal

Fig 347—Fracture of metacarpal bone showing flexed position with dorsal projecting spur

mal fragment is brought about by the action of the interosseous muscle while dorsal displacement of the distal fragment is due to the action of the lumbrical muscle. Here again fixation on a straight splint will maintain the deformity and result in impaired function. When the distal fragment is brought into line with the proximal frag

ment by fixation on a curved splint a minimum of deformity will result

Fractures of the metacarpals (exclusive of the thumb) usually result in typical deformities characterized by shortening of the length of the bone due to bowing of the fragments. There is a dorsal projection at the site of fracture and volar displacement of the metacarpal head (Fig 347). This deformity is the result of the action of the interosseous muscle which is a flexor of the proximal phalanx. The distal fragment of the metacarpal being attached through the metacarpophalangeal joint to the proximal phalanx is drawn into a flexed position.

The treatment of these fractures requires

phalanges in contradistinction to the other metacarpals which have distal epiphyses. Its fractures may be classified as follows (Fig 348)

- I At the base
 - (a) Intra articular
 - 1 Bennett type
 - 2 Rolando type
 - (b) Extra articular
 - 1 Transverse
 - 2 Oblique
 - 3 Complicated
- II The shaft

- III The head
 - 1 Transverse

Fig 348—Fractures of the first metacarpal bone

immobilization on a straight dorsal splint to restore the normal horizontal contour of the dorsum of the hand. Fractures of the third and fourth metacarpals are splinted laterally by their adjacent metacarpals. The second and fifth when fractured require dorsal splinting and in addition lateral splinting.

Fractures of the first metacarpal are of importance because of the value of the thumb in the usefulness of the hand. The first metacarpal has the movements of a proximal phalanx which indeed it resembles. It has a proximal epiphysis as have the

The treatment of fractures of the first metacarpal is of importance because of the associated pathologic condition which develops. Faulty union, atrophy of the muscles of the thenar eminence and weakness of grip all contribute to the disability which may follow a simple fracture. In all of the extra-articular types fixation in a position of extreme abduction will return the web of the first metacarpal space and permit abduction when the splint is removed.

In the Rolando type of fracture simple abduction is usually sufficient to produce ap

proximation of the fragments of the bone. The prognosis in this type of fracture is better than in the Bennett type because of the absence of upward dislocation of the shaft which is usually found in the Bennett type. In this latter type special effort must be directed to overcome the pathologic displacement. In addition to the extreme abduction suggested for the other types of fracture longitudinal traction is essential if upward dislocation of the shaft has occurred. The incorporation of a wire loop in a plaster cast about the wrist has been utilized as a means of support of longitudinal traction produced by means of adhesive strips and rubber bands.

A summary of the metacarpal and phalangeal deformities with general principles of management is illustrated in figure 345. It is evident from these illustrations that the principle of aligning the mobile distal fragment with the less mobile proximal fragment is applicable to all fractures of the bones of the hand. This simplifies the essentials of treatment and relieves the surgeon of the necessity of keeping in mind the details of the mechanism involved in the various displacements.

The materials used in the maintenance of these corrected positions are those commonly used in other fractures: tongue depressors, strips of aluminum, adhesive tape and roller bandages of various sizes.

In all applications care should be taken to preserve the blood supply to the part. The necessity of frequent examinations and the avoidance of undue pressure or constriction cannot be overemphasized.

Compound fractures of the metacarpals and phalanges occur very frequently. One must decide at once in these injuries the character and extent of the damage and plan their treatment to the end that the patient will have the best functioning hand which can be salvaged. If the soft parts are greatly damaged the operative manipulation of the fracture may serve to contaminate the wounds or impair the vitality of the tissues still further. In these cases the surgeon may be compelled to restrict his activities to a thorough debridement coupled with the simplest of corrective splinting and dressing. As the patient improves a constant attempt should be made to restore the mem-

ber and its injured parts to a position which will insure ultimate usefulness.

RAYMOND W. MCNEALY
MAJOR MANUEL C. LICHTENSTEIN

FRACTURES OF THE VERTEBRAL COLUMN

Definition.—Because of major differences in importance, treatment and etiology these fractures fall into three main groups: (1) fractures of the body (centrum) including those of the laminae and the articular and spinous processes; (2) fracture-dislocation; and (3) fractures of the transverse processes. The importance of the fractures in groups 1 and 2 lies not alone in their effect on structure and function but on the circumstance that the spinal cord is contained within injury to which is so often irreparably crippling or fatal.

Incidence.—About 6 per cent of all fractures and dislocations fall in these groups and half of these are of the transverse process. The ratio of body fractures to dislocations is approximately one to fifteen. The age incidence is greatest in the fourth and fifth decades.

Etiology.—The immediate causes are in direct external violence and muscular action. Commonly a fall from a height, a blow from a heavy object falling on the shoulders when the spine is flexed, an automobile accident or a diving injury produces the fracture.

Pathology.—The fractures in groups 1 and 2 result from violent hyperflexion either forward or lateral, the body of the vertebra being crushed into a wedge or saucer-shaped deformity. In most instances (80 per cent) the intervertebral disk is ruptured and disorganized. Commonly one or more of the posterior bony processes are fractured. If the flexion force is then not spent, dislocation of the vertebra above occurs. The cord may be damaged either through elongation or as a result of narrowing of the lumen of the canal caused by pressure of bone or hemorrhage incident to the fracture.

In group 3 the fracture is transverse and often several processes are involved.

the posterior portion of the vertebral body is intact—approximately 90 per cent.

E Technic of Reduction of Wedge Compression Fracture of Vertebral Body (no dislocation posterior portion of vertebral body intact)—The keynote of successful reduction is complete hyperextension of the vertebral column. By this means the compressed fragments of the crushed body are drawn into normal relation by the pull of the longitudinal ligament. The two ends of the posterior ligaments are approximated. Anything short of complete hyperextension will fail to effect reduction. It is the last few degrees of hyperextension that actually produces reduction.

which are convenient. Among these are the suspension³, the flexible frame², the sling traction⁴, the Goldthwait irons and the table methods⁵. The following technics represent a modification of several of these. Each fulfill the requirements of a sound method and is simple and the apparatus is within reach of all traumatic surgeons.

Choice of Method—The problem of reduction in the lumbar region is much easier than that in the dorsal. A three day old fracture in any region can be more easily corrected than one that has been unreduced for a week or longer. A fracture involving the posterior wall of the centrum requires powerful traction during extension if it is

FIG. 349.—A convenient type of hammock frame. The canvas hammock is operated by means of a ratchet and pawl so that it is always under the complete control of the surgeon.

Anesthesia—A general anesthetic should not be used. It is dangerous and unnecessary. Morphine and scopolamine given hypodermically will produce sufficient relaxation of the muscles and will allay apprehension. The dose varies with the patient's age and weight. For an average adult $\frac{1}{4}$ gram of morphine and $\frac{1}{100}$ grain of scopolamine in two doses one hour apart should be satisfactory.

Methods of Reduction—There are a number of efficient methods of producing spinal hyperextension. Only those should be employed which are under absolute control which do not require an anesthetic and

decided to attempt reduction so that the posterior fragments will not be pushed backward against the cord or nerve roots during reduction. The reduction of a vertebral dislocation is always dangerous and requires a special and sometimes elaborate technique. Therefore each fracture should be carefully analyzed with these points in mind and the method selected so as to meet the requirements of the individual case.

1 Common Wedge Compression Fracture of a Lumbar or Eleventh or Twelfth Dorsal Vertebral Body (Without Cord Injury)—No dislocation is present and the posterior wall of the body is not involved.

The Suspension Method (Davis)—The patient, relaxed by morphine scopolamine and with the trunk covered with stockinette is placed face down on a canvas webbing band 8 inches wide which has been drawn taut lengthwise along a fracture table or Bradford frame equipped at one end with a ratchet and pulley device as shown in figure 349. The webbing is split at the head end to provide for the patient's face. The ankles are heavily padded with sheet wadding and ankle slings are applied over this. A pulley block and tackle is fastened to the ankle slings preferably by a spreader. The other pulley block is fixed to a point opposite the knees and high above the frame or table. The lower extremities are gradually raised by means of the block and tackle (Fig. 350). This maneuver is carried out slowly especially at the start, to

reach the physiologic limit the fracture is thereby reduced. Thereafter the angulation can no longer be seen or felt. Occasionally, however, this may not be the case because extension seemingly carried to the limit is actually less than complete. The period of suspension should then be prolonged to overcome muscle spasm, after which gentle manipulation of the trunk from side to side while the patient is still suspended or gentle downward pressure by the surgeon's hands may be necessary to disengage impacted fragments. A plaster jacket is then applied with the patient in suspension. As quickly as this has dried the traction is released the canvas hammock is cut and withdrawn and the patient is returned to bed.

The Plaster Jacket—The plaster of paris jacket (Fig. 353) is applied while the patient is on the ham-

Fig. 350—The suspension method (Davis) of obtaining spinal hyperextension combined with traction. The patient is placed face downward on the hammock. The lower extremities are gradually raised by means of the block and tackle. The surgeon is thus able to extend the spine gradually while the correcting forces are always under complete control. The felt padding may now be arranged about the torso and the jacket applied. This method is particularly indicated in fracture of a lumbar or the eleventh or twelfth dorsal vertebra.

overcome muscle spasm and with frequent pauses during which the function of the cord may be checked by having the patient move his toes. Increasing pressure on the cord during reduction is heralded by motor weakness and pressure on the nerve roots is heralded by shooting pains in the lower extremities. Both are preceded by severe pain at the site of the fracture. Since a general anesthetic is not used injury to the cord during reduction can therefore be readily avoided. The limit of hyperextension is reached when the pelvis and the lower portion of the abdomen have been raised several inches above the canvas sling, the thighs make with it an angle of about 55 degrees and lumbosacral backache becomes persistent. The reduction requires but a few minutes. In order to confirm the reduction roentgenograms may then be taken while the patient is still suspended. When hyperextension has been car-

ried to the physiologic limit the fracture is thereby reduced. Thereafter the angulation can no longer be seen or felt. Occasionally, however, this may not be the case because extension seemingly carried to the limit is actually less than complete. The period of suspension should then be prolonged to overcome muscle spasm, after which gentle manipulation of the trunk from side to side while the patient is still suspended or gentle downward pressure by the surgeon's hands may be necessary to disengage impacted fragments. A plaster jacket is then applied with the patient in suspension. As quickly as this has dried the traction is released the canvas hammock is cut and withdrawn and the patient is returned to bed.

After Care—The jacket should be worn for about three months. During this time the patient's weight

should be watched, since any considerable loss renders the jacket inadequate. If the centrum was severely crushed, it is well to continue the use of the jacket for

convex portion of the curve of the vertebral column, the weight will be carried on the posterior wall of the centrum, and the patient should be ambulatory. If,

Fig. 331. *a*,—Fracture of the vertebral body with injury of the intervertebral disk. *b*, Position after reduction by hyperextension.

Fig. 332—*a*, Central compression type of vertebral fracture. *b*, Position after attempted reduction. Little or no decompression can be obtained.

another month or more. The patient with a jacket may be ambulatory provided the weight above the fracture falls on the intact posterior portion of the centrum. In other words, if the fracture lies in the anteriorly

however, this requirement is not satisfied, if there is lateral crushing or if the patient is obese, the same treatment should be carried on but with the patient recumbent. A plaster of paris shell may occasionally

be necessary. After the period of jacket fixation, a belt may be worn for about a month during which time exercises should be vigorously pushed.

Exercises.—Active spinal extension and abdominal retraction should be started a few days after the reduction and kept up throughout the time of treatment. As fixation is being gradually withdrawn, lumbar flexion and pelvic rotation must be insisted on so as to obliterate the deep lordosis resulting from the hyperextension necessary to correction and fixation, otherwise, backache will ensue. By means of these exercises the ideal of treatment is achieved, whereby a normal range of motion and muscle strength are gained by the time the bone union is complete. In this way the patient is spared long periods of rehabilitation and discomfiment.

2. Fracture of Upper Dorsal Vertebrae (above the Eleventh) (Without Cord Injury).—The difficulties involved in the reduction and fixation of the fractures in this region are so considerable and the results without reduction are so satisfactory that correction of the deformity is commonly not indicated. Instead, eight weeks of recumbency on a firm bed and intermittent head traction through the halter and extension exercises, to keep the cervicodorsal junction limber, are commonly employed for about six months.

3. Cervical Body Crush Fracture (Without Cord or Root Injury).—No dislocation is present, and the posterior wall of the body is not involved.

Reduction is obtained by hyperextension. The surgeon, holding in his hands the patient's occiput, gently lowers the head over the end of the operating table until reduction is complete, as verified roentgenographically. Anterior and posterior shells are then made, being carefully molded to the head, neck, torso and thighs. Spinal fusion is justified to eliminate sequelae.

4. Fracture of Odontoid Process.—Because of the peril of dislocation of the atlas on the axis, with consequent crushing of the spinal cord, adequate fixation is imperative. Gentle skeletal traction (5 to 15 pounds) applied through tongs^{8, 9} or wires¹⁰ will prevent disaster. Internal fixation and fusion of the atlas and the axis is justifiable; otherwise a plaster jacket which includes the head and neck should be worn for at least four months, followed by a Doll or Thomas collar for several months more, until union of bone is demonstrated roentgenographically.

5. Cervical Fracture-Dislocation.⁷—

Skeletal traction (10 to 30 pounds), applied through tongs^{8, 9} or wires,¹⁰ must be instituted as soon as the diagnosis is made. By it, further risk of cord or root injury is avoided; if nerve trauma is already present, further injury is avoided. Reduction is occasionally effected by this means alone. If by the traction, reduction is not complete, open reduction may be done under traction. This should be done only by those who are thoroughly competent. The procedure is difficult and demands special skill and an intimate knowledge of the pathologic changes. Inter-

Fig. 533.—Diagram showing the extent of the plaster jacket used in the treatment of lower dorsal and lumbar vertebral fractures.

nal fixation and fusion is justifiable. Without fusion, recurrence of the dislocation (sometimes fatal) is not uncommon.

If, unfortunately, skeletal traction is not available, the Walton-Taylor manipulative reduction is indicated.

Walton-Taylor Reduction.¹¹—The patient, deeply anesthetized, lies on the operating table as for reduction of a simple fracture. A traction head halter is applied and is fixed by a band around the waist and back of the operator, who stands at the patient's head and exerts traction throughout the maneuver by leaning gently backward against this band. (1) The rotational deformity is gently increased if it is in a right unilateral dislocation forward, the turn of the head is to the left. (2) The head is tipped gently away from the dislocated side. (3) The neck is gently hyperex-

tended and the head is turned to the front. A click audible to or felt by the operator often announces reduction. The ability of the patient to turn his head freely back to the initial position demonstrates reduction. When the dislocation is bilateral the reverse maneuver is carried out for the other side. Fixation and after treatment are the same as those for simple fracture.

6 Fracture of the Transverse Process

—This type of fracture is frequently regarded as a grave injury but this is erroneous as such a fracture is in reality a minor injury. A firm adhesive plaster stripping, removed and renewed at five day intervals for several weeks is indicated. Rest in bed

done with the greatest care may result in damage to the cord or the nerve roots.

Reduction may be attempted by the suspension method (previously described) provided in the anteroposterior roentgenogram taken immediately before no disalignment of the posterior articular processes is seen (Figs 354 and 355). If the procedure is carried out slowly and without a general anesthetic the surgeon should be able to detect impending injury to the cord or nerve roots in time to avert irreparable damage. At the first sign of pressure on the cord or nerve roots the extension must be stopped and the

Fig 354

Fig 355

Fig 354—Fracture-dislocation of the spine. Hyperextension without distraction is dangerous to the cord.*

Fig 355—Post on after reduction of fracture-dislocation of the spine.*

for one or two weeks is sometimes necessary when several processes are broken. Rarely extensive hematoma makes a plaster jacket or shell necessary. Attempts at reposition of fragments are not successful and are unnecessary. When healing is well advanced usually in two or three weeks exercises should be started. The period of disability usually lasts for one to twelve weeks.

DISLOCATION (DORSAL AND LUMBAR)¹¹

Reduction of a vertebral dislocation may be difficult to accomplish and when it is not

spine gently returned to the position present before extension was begun. A jacket is applied to safeguard the back until open reduction can be performed.

If, however, anteroposterior roentgenograms taken immediately before reveal lateral disalignment of the spinous and articular processes, manipulative reduction should never be attempted since cord or cauda damage may result.¹¹ Immediate open reduction is indicated.

Failure by extension to reduce a dislocation in such cases is due to locking of the posterior articulations. These processes can

* Rogers Arch Surg 30

be freed by open reduction, a procedure which may prove very difficult. It should not be attempted by those not fully equipped and trained in neurosurgical technique. For this operation a local anesthetic should be used. As soon as the facets are freed (by flexion obtained by lowering the ends of the operating table) and realigned (by levering the posterior processes with a skill aided by the appropriate derotation of the trunk by a skilled assistant), the spine should be hyperextended and the jacket applied.

The after-care following reduction is the same as that for fracture.

Prognosis and End-Result.—The treatment of these fractures has within the last 10 years been raised to a level of efficiency on a par with that of most other fractures. When the condition is diagnosed early, when anatomic restitution is secured and when early active motion and adequate fixation are provided a return to full pre-injury activities in six to eight months is obtained in 65 per cent of the cases. This means that the normal healthy person who is properly treated may be expected to be as well six months from the time of injury as he was before the accident.

Late Changes in the Fractured Vertebral Body and Intervertebral Disk.—The disorganization of the disk as a result of injury is followed by the development of replacement fibrosis. Since scar tissue is incapable of withstanding sustained pressure, much of the intervertebral space is lost, the loss being definite in 85 per cent of the cases. The normal local mechanics change with this alteration in structure, and there results loss of adaptability to changing stress and strain. Bone proliferations appear along the margins of the centrum, and the articular end-plates become denser. Some of the proliferations rapidly develop and in over 40 per cent of the cases form a complete bridge of bone across the intervertebral space, thus uniting the fractured with the adjacent vertebra. The vertebral column is so adaptable that these local changes have little or no effect on function as a whole and are usually not appreciable clinically, provided correction of the deformity of the vertebral body has been maintained.

FRACTURES OF THE PELVIS

Fractures of the pelvis are best classified as follows:

- 1 Those that involve the ring: (a) At one point of the circumference, (b) at two or more points of the circumference without displacement and (c) at two or more points with displacement upward of one side.
- 2 Fractures that involve bones entering into the formation of the ring, but the ring remains firm and unbroken, i. e., the iliac crest or wing the spine of the ilium, the tuberosity of the ischium and the acetabulum below the sacrospinous articulation.
- 3 Acetabular fractures: (a) involving the rim (b) involving the three segments and (c) perforating.

Etiology.—Some great force is always necessary for the production of a fracture of the pelvic ring, because this structure is strong and elastic. Prior to the age of rapid transit, falls from a height and crushing between logs or heavy bales of goods were the common causes of this injury. At the present time crushing between railroad cars, trucks or automobiles is the major cause, although there are many cases on record of persons who have sustained pelvic fractures while riding in a closed car when there has been a collision and the occupants have been thrown violently together, either by the force of the collision or by the overturning of the vehicle. The injured person in this type of accident seldom remembers the exact nature of the force that caused his injury. However, Malignaigne records a case of a fall from a height on an extended limb which caused

a fracture-dislocation upward of the same side of the pelvis.

In cases of isolated fracture of the anterior superior spine, the crest or the wing of the ilium, and avulsions of the ischial tuberosity, an exact history may be obtained. Blows or kicks on the perineum and a fall

lesion, and one entire side of the pelvis may be dislocated upward for from $\frac{1}{2}$ to $3\frac{1}{2}$ inches. This is called a *Malgaigne fracture* and is always very serious. The force necessary to cause it is so great that as a rule there is a high mortality rate, due both to the fracture and to the associated injuries. The fracture line through the posterolateral portions of the pelvis may be associated with a separation of the symphysis pubis, instead of a fracture through the bones forming the obturator foramen, and may be associated with a more or less true sacroiliac dislocation. But these conditions are not very common. It is extremely rare to see a fracture alone or in any combination that extends up through the middle of the sacrum.

Fractures of the iliac crests are very common. Avulsions of the anterior superior spine of the ilium or of the epiphysis of the ischial tuberosity are uncommon.

Fig 336—Fracture of the pelvis during pregnancy, which was not disturbed

across a fence or rail or on the tongue of a wagon are frequent causes of fractures of the inferior ramus of both pubis and ischium. On the whole the average person with a fractured pelvic ring has other serious injuries and a patient with multiple injuries must always be examined for a fractured pelvis and the visceral complications that so commonly accompany this lesion.

Pathology.—The pelvic girdle is most frequently broken through the bones forming the obturator foramen and of these the rami of the pubis and the inferior ramus of the ischium are by far the most commonly involved. The superior ramus of the ischium is rarely injured in this type of pelvic fracture, but it is not uncommon to find bilateral fractures through each obturator foramen. These fractures through the obturator foramen may be the only fractures present, but there may be a fracture through the posterior portion of the ilium or the sacroiliac joint or sacrum which accompanies this

Fig 337—Fracture of the pelvis with involvement of the acetabulum and dislocation of the femur

Fractures of the acetabulum are steadily increasing in frequency, both because more are recognized and because more occur. They may be classified as follows:

A Fractures of the rim:

1. An oblong fragment on the posterior Ep of the acetabulum essentially that position contributed by the ischium in its development.

- 2 An oblong fragment essent ally that portion contributed by the ilium
- 3 An oblong fragment, essent ally that portion contributed by the pubic bone
- B Fractures of the acetabulum involving one or two of the three bones which form it
 - 1 Fracture with displacement inward and backward of the ischial segment and ramus
 - 2 Fracture with displacement inward of the pubic segment and ramus
 - 3 Fracture with displacement of both the pubic and ischial segments with ramus
 - 4 Fracture with displacement upward and backward of the ilial segment
- C Perforating fractures

In this type the lead is forced through the bottom of the acetabulum with a very small amount of the surrounding bone
- D A fracture so extensive that all of the bones are involved and fragmented

The urethra and the bladder which lie in such close proximity to the pubic bones are frequently injured these complications often occurring with fractures that have not required much force. The rectum is not often injured but when it is the infection from it is so violent that it is usually fatal. The small intestine and sigmoid are less commonly involved. Injuries of the greater blood vessels are not unusual and when present are frequently fatal. There is a marked extravasation of blood in every pelvic injury, and this blood is almost always extraperitoneal sometimes extending over the lower part of the anterior abdominal wall. Often there is free blood in the peritoneal cavity resulting from an injury to the overlying peritoneum but without any injury to the viscera.

Symptoms—Any person whether conscious or unconscious who has sustained a fracture of the pelvis must be examined for other injuries. If this procedure is carried out in the admitting ward many lives will be saved. The best possible history of the accident and of the force involved should be obtained. Points of tenderness over the pubis, ischium, ilium and sacrum must be looked for carefully because sometimes the patient is too benumbed to be cognizant of pain but will react promptly to pressure on a point of tenderness. If the patient complains of any definite pain such a history should not be belittled because it is a most valuable symptom and will be of great aid in reaching a diagnosis.

Fortunately for the patient but unfortunately for the surgeon who is endeavoring to make a diagnosis the average person with a pelvic fracture will complain only on moving, being moved or having pressure applied over the area of bone injury. Careful palpation and inspection of the perineum are imperative in these cases and a rectal examination should be made with the finger carefully exploring around the inferior ramus of the pubis and ischium and well up on the superior ischial ramus. The convexity of the sacrum can also be outlined with the finger in the rectum but great care should be taken not to injure the rectal wall on any sharp spicule of bone because any perforation would free the violent pathogenic bacteria which are found in this segment of the intestinal tract. Gas forming bacilli are commonly present in the lower intestine and if they are freed into a large retroperitoneal hematoma they may cause a fatal infection. The superior ramus of the pubis cannot be accurately palpated but a marked point of tenderness with swelling and discoloration is very significant of bone injury. Rather large hematomas are common in injuries of the iliac crests and there are times when the evacuation of these great masses of blood by an incision will be of value. No drainage should be used. Deformities of the pelvis caused by crushing and displacement are common but they must be carefully sought for as they are not easily observed. Even when one pubic bone is dislocated up and over the one on the opposite side in a person of moderate size it does not cause an easily detectable deformity. A deformity caused by a $\frac{1}{4}$ to 2 inch displacement of one side of the pelvis in a case of Malgaigne fracture has no great degree of visibility and must be carefully sought for by having the limbs parallel and the feet together. The surgeon must not take too much for granted after making a hasty inspection. Loss of function is variable in minor fractures but is always present in a severe fracture and the patient is helpless so far as pedal locomotion is concerned. The writer has never been able to prove to his own satisfaction the presence of a simple subluxation of the symphyseal joint.

Genitourinary Symptoms—A small amount of blood in the urine is commonly

found in these injuries and may arise in the kidney bladder or urethra it is always an ominous symptom. Its origin must be determined as rapidly as possible considering the degree of shock in which the patient

and the bladder contains only a little bloody urine it is highly probable that the bladder has been ruptured and an exploratory operation is indicated at the earliest moment. A diffuse tenderness and semi rigidity of the

Fig 358—Severe fracture of the pelvis with central dislocation of the femur through the fractured acetabulum

may be it must also be borne in mind that a severely shocked patient does not pass much urine. The continuity of the urethra should be noted and the amount and character of the urine obtainable from the bladder should be ascertained at the earliest possible oppor-

timunity. The abdominal wall may arise from an extravasation of blood in the peritoneal space but marked tenderness and rigidity of the abdominal wall with scanty, bloody urine almost always indicate that there is either intraperitoneal or extraperitoneal rupture of

Fig 359—Same case as shown in previous figure after reduction

tunity. The test should be repeated at short intervals if there is any doubt as to the extent of the injury. If the bladder has been ruptured it is usually almost empty and blood is certain to be present. If the abdominal wall is rigid semi rigid or very tender

the bladder. Occasionally 3 or 4 ounces of urine can be obtained from a ruptured bladder but it is not common as the pressure of the abdominal cavity on the fundus of the bladder prevents the expansion of the bladder wall and the urine is thrown out freely

into the peritoneal cavity or less freely into the peritoneal space. If the rupture is extraperitoneal the lower portion of the abdominal wall will be swollen and boggy, not infrequently the scrotum in the male and the labia in the female are swollen and edematous. These findings may be corroborated by the injection of a sterile solution into the bladder and noting the amount that is recovered. If the entire amount of injected fluid is not recovered it is proof that there is an injury to the bladder wall. This test is of value when shock is so marked that little if any urine is being secreted. Another procedure is the injection of air into the bladder and the use of the fluoroscope or the x-ray plate to determine whether the bladder is distended or whether the air passes into the abdominal cavity. The objection to the injection of sterile solutions is that it may cause the spread of any infection that may be present. The objection to the injection of air is that in a certain number of cases death will result from air emboli.

Symptoms in Acetabular Fractures.—Fractures of the acetabulum of a minor type such as of the rim without the involvement of a displaced segment are extremely difficult to diagnose from the physical findings. Fractures either of the pubic segment or of the ischial segment without marked inward displacement are also extremely difficult to detect by physical examination. The following signs are of great value: a marked inward displacement or a central dislocation, the flattening of the trochanteric region, the limb in that case being of normal or increased length, the limitation of abduction and the extreme pain on abduction or any other movement of the thigh. If rectal examination reveals tenderness high upon the side of the injury with more or less boggyness due to extravasated blood and joint fluid, one can be almost certain of the condition present. The final diagnosis, however, must depend on a very careful roentgenologic examination with several plates taken from various angles.

Diagnosis.—The actual diagnosis of a fracture of the pelvis is not difficult if the surgeon makes a careful physical examination and checks this with roentgenograms. Complications such as the rupture of a vessel or one of the great vessels will be the

cause of grave concern to determine the correct line of treatment.

Prognosis.—A search through the literature on fractured pelvis discloses a marked variation in the mortality statistics. In those cases in which a definite diagnosis of fracture of the pelvis was made either clinically or by postmortem examination there was a mortality of from 10 to 37 per cent. Many cases of fractured pelvis are overlooked under the vague clinical diagnosis of internal injuries, such as ruptured kidney, ruptured spleen, ruptured liver, etc., but an autopsy in these cases frequently reveals that the true cause of death was a fractured pelvis. The prognosis as to disability varies. As a rule the healthy patient with a fractured pelvic ring is in good condition at the end of four months or even less, but in an industrial case with medicolegal complications there is an average of from six to eight months of temporary total disability with varying degrees of partial permanent disability (usually not truly permanent).

Treatment.—The average fracture of the pelvic ring involving the ramus of the pubis and ischium with little or no displacement will heal perfectly and function is restored in twelve weeks. The patient spends from five to seven weeks in bed without any particular dressing and then is allowed to be up and around for from three to five weeks after which he may resume any ordinary occupation. If his occupation requires heavy labor at least sixteen weeks must elapse before he may return to work. If there is a wide separation of the fragments (about one in seven cases) the patient may be suspended in a sling. If this separation is in a muscular man a broad heavy band of molskin adhesive plaster placed below the crests of the ilium and over the trochanters of the femur may give adequate support and great comfort. But in a fleshy man or woman an adhesive band is as a rule unsatisfactory because its edges roll up and irritate the skin. The patient may be suspended in a hammock attached to a Balkan frame. The supports of this hammock may be hung vertically or if necessary can be crossed above so as to increase the lateral pressure on the displaced fragments. Too much lateral pressure with multiple pulleys and with the ropes crossed from side to side can easily crush a

pelvis and is a source of danger. This type of treatment must be used with the greatest possible care.

If there is a displacement over one side of the pelvis—a *Malgaigne fracture*—every possible effort must be made to reduce the displaced fragments into position. This may be accomplished by traction on the injured limb of 50 to 75 pounds of weight with a counter pull through a belt beneath the opposite tuber ischi. If this is not successful the patient should be placed on a Hawley table and extension made with the screw traction with the firm side of the pelvis fixed against the center post and extension made on the opposite extremity. The writer has succeeded in reducing one fracture of this type that was of ten days' duration by fixing the limbs in the Hawley table and then manipulating the torso, abducting it from the injured side. An avulsion of the anterior superior spine of the ilium of an ischial tuberosity is sometimes so painful that replacement and fixation are required. A fracture of the crest of the ilium seldom requires any type of treatment other than the aseptic evacuation of a large hematoma. A fracture of the sacrum is best treated with rest and quiet, the prone position being the most comfortable. Dislocation of one pubic bone over the other is rare but should be reduced by manipulations or open operation as the pain and discomfort without reduction are sometimes very severe. A true dislocation of the sacroileal joint has been very uncommon in the writer's experience. A fracture of the acetabulum should be accurately diagnosed and carefully treated as it will be the cause of very serious disability if not corrected. To adduct and extend the limb of the injured side will be sufficient to reduce the usual displacement if treatment is begun early. In some cases a band around the thigh with lateral traction in addition to the longitudinal traction is sufficient. In other cases it is necessary to drive a large screw into the neck of the femur and thus make adequate lateral traction. In other cases the head of the femur is driven through the acetabulum and the fragments lock the head into position so that an open operation is required to release the femoral head. It can then be held in position with longitudinal traction. From ten to fourteen weeks of recumbency are

generally required. Each of these methods and means may be necessary in some certain complicated conditions and there are times when the damage has been so severe that any manipulation or extension whatsoever is precluded. When there is doubt about the presence of a rupture of an abdominal viscus an exploratory operation should be performed.

WILLIAM R. CUBBIN

FRACTURES OF THE FEMUR

General Considerations.—Fractures of the femur constitute an important group with a high percentage of disability. The disability percentage is too high in the light of present-day knowledge and experience and the attempt will be made in this article to present as clearly as possible the modern concept of the handling of the various groups into which femur fractures can be conveniently divided and the factors involved in the choice of methods for the individual case. Details of treatment methods must necessarily merely be indicated when the method is particularly involved. No attempt is made to present statistical studies. Their value is largely academic and their application to the individual case is hard problematized.

The essential idea underlying the treatment of all fractures is the function of the part. In the lower extremity it is primarily that of weight bearing and shifting of weight bearing known as locomotion. This makes the aim of treatment quite different from what it is in the upper extremity in which flexibility and range of motion are the essentials. Although an inch of shortening or a 10 degree angular deformity in the humerus is of no functional significance, it becomes of vital importance in the lower extremity. The best evaluation of the importance of this concept lies perhaps in a comparison between our attitude toward fractures of the surgical neck of the humerus where the head is angulated somewhat but impacted and a similar condition in the neck of the femur. The two bones are analogous with heads offset on the shafts by an intervening neck. The femoral neck is merely somewhat longer than the humeral one. In the first case the deformity is not disturbed early even immediate active function is

tutted and rapid return of a normal range of motion and flexibility is sought. In the second instance considerable risk is taken to secure adequate anatomical restoration even breaking up impacted angulation and prolonged immobilization are practiced to maintain corrected position with risk to life and the range of joint motion. The difference in practice is due to the difference in the aims of treatment based primarily on the function of the part. Of course it is desirable to maintain all the motion possible in the lower extremity—in fact this has been the driving force in developing modern methods of treatment, but the functional anatomy is of prime importance.

With this concept of therapeutic aims fractures of the upper extremity of the femur will be considered as one group fractures of the shaft as a second group and fractures of the lower end as a third group.

FRACTURES OF THE UPPER EXTREMITY OF THE FEMUR

There is considerable comfort in the fact that a *laissez faire* attitude, visions of and bags and a hopeless prognosis are no longer considered part of the picture presented by fractures of the femoral neck. Today the case which justifies such a viewpoint and course of procedure is a rarity. True there is still much room for improvement but as a result of the investigations of the problem in the last twenty years not only has a great deal been accomplished but further advances leading to still lower mortality and better results may be confidently looked for in the next decade.

Past present and future victims of this deplorable fracture owe an immeasurable debt to Royal Whitman for his militant missionary work in this field. No one person has been so important a factor in forcing intelligent and progressive study or has contributed so much to aid in that study. In addition to the contributions and influence of Dr. Whitman we have today in our attack on the problem the aid of increasing knowledge of the anatomical characteristics of the part of the value and significance of adequate roentgen studies both before and after reduction of the wide variations in the initial pathology and of the course and character of the healing process.

It may seem that an inordinate amount of space is devoted here to anatomy and pathology but a knowledge of the essential anatomy of the femoral head and neck and their soft parts and of the pathology of the various fractures is of paramount importance in the formation of any intelligent plan of treatment.

In figure 360 I it will be noted that there are five sources of blood supply to this general bony region: the ligamentum teres, the vessels accompanying the capsular attachment to the neck, those accompanying the reflection on to the neck of a thin layer of capsule together with synovia up to the articular edge, the nutrient vessels at the base of the neck and a multitude of small vessels derived from the muscular attachments about and along the intertrochanteric region entering via the periosteum. These latter constitute in point of total volume a large part of the circulatory supply to the intact bone. The intact neck of the femur is then far from deficient in circulation. The complicating factor lies in the fact that all or the major part of the circulation to a fracture site must often be derived from soft part sources outside the bone and not from its intrinsic or nutrient vessels once fracture has occurred. Comparison of figure 360 I and II demonstrates what occurs as regards circulation in the various regions of the femoral neck following fracture.

Assuming each fracture line to be complete with tearing of all vessels across the line of fracture it is readily seen that when the fracture occurs across line 1 the so-called subcapital fracture the proximal fragment has for its blood supply only those vessels small and few in number which enter through the ligamentum teres. In some instances this ligament contains no vessels which actually reach the head of the bone. At all events the head is cut off from B, C, D and E as sources of circulation. If the fracture occurs between lines 1 and 2 the proximal fragment has as an additional blood supply only such circulation as has remained intact by reason of untransected portions of capsular reflection. While it is true that the circulatory supply B of the capsular attachment itself is profuse the reflection of the capsule on to the intracapsular portion of the neck is extremely thin in

places practically lacking so that circulation C at the best is scanty and if there is separation of the fragments to any degree this circulation becomes nil as regards the proximal fragment. The head is then no better off than following subcapital fracture. When the fracture occurs between lines 2 and 3—the so called base of the neck—the proximal fragment retains circulations A and C plus those vessels from sources B and D which lie proximal to the fracture line. When the fracture lies between lines 3 and 4 the proximal fragment retains circulations A B C D and all of the rich circulatory supply E will be discussed.

supply unless extensive retrograde thrombosis occurs following fracture. It is also obvious that in any given fracture all the vessels crossing the fracture line may not be ruptured or thrombosed and that in subcapital and intracapsular fractures the capsular reflection may not be completely torn.

Apart from the problem of the actual life of the proximal fragment, studies of bone repair have pointed out the varied significance of adequate circulation in that process.

It is therefore advisable to remember from the standpoint of prognosis that it is impossible to state at the outset for the specific case of intracapsular fracture how much cir-

Fig 360—I Sources of blood supply for the femoral neck. A From the ligamentum teres scant and sometimes missing. B from the capsular attachments numerous large vessels. C from the capsular reflection and avulsion small short vessel. D nutrient vessels numerous and good sized. E from the extensive muscle attachments in intertrochanteric region (shaded area). In the intact femur these vessels anastomose freely. II (compare with I) Effect of fracture on blood supply to the proximal fragment. Assuming the fracture to be complete in each instance the proximal fragment retains after: Fracture 1—blood supply 1 only. Fracture 2—blood supply A plus C. Fracture 3—blood supply A plus B plus C plus D. Fracture 4—blood supply practically intact.

These two latter fractures lying between lines 2 and 3 and 3 and 4 are a separate group clinically except for the physical signs and symptoms. The prognosis and treatment are entirely different from those of the first two groups. The latter will be considered first under the designation of intracapsular fracture and later the differences presented by the two other groups under the terms base of neck and intertrochanteric fractures will be discussed.

INTRACAPSULAR FRACTURE

(Subcapital and Through the Neck)

It is of course obvious that in all instances the distal fragment has an adequate blood

supply. The prognosis must necessarily wait until the extent of circulatory damage becomes apparent in bone changes noted in the roentgenograms. This is a question of weeks not days.

In addition to the pathology involving circulation in these fractures one must also keep in mind the fact that there is no characteristic displacement of the fragments. There may be no displacement at all, merely a crack showing across the bone. When the fracturing violence is directed against the greater trochanter which is unusual the displacement is apt to be that of a varying degree of impaction with a tendency to cox valgus (Fig 361 3).

Tearing of the soft parts and primary circulatory damage theoretically should be at a minimum in these two groups of cases although secondary thrombosis of vessels may eliminate this favorable factor. Ordinarily the displacement, when it is present is the result of a variable amount of downward force of the pelvis exerted on the head plus a torsional force due to twisting of the body. This results in various degrees of *coxa vara*

It is apparent that the damage to the various circulations is more complete with the increasing degrees of displacement, since this predetermines more and more tearing of the capsular reflection and of the attached soft parts.

In the higher fractures the intracapsular and the subcapital actual death of the proximal fragment may occur a condition which Phemister has called aseptic necrosis

Fig 361—3 Fracture following violence against the trochanter. Dotted line represents normal position of the head. Shaded area represents impaction. It will be noted that the pull of muscles running from the upper femur to the pelvis and trunk tends to impact the position further (force B) and that weight bearing has the same tendency (force C). Compare with the effect of these forces in the normal neck (4) and in the presence of fracture with *coxa vara* deformity (5).

4 Forces involved in production of the usual deformity in fracture of the femoral neck. A Downward force of the body via pelvis after stumble. B resistance of fixed leg and foot. C variable pull of muscles running between thigh and trunk. B and C both tend to augment action of A (compare with 3). D torsional force tending to produce horizontal angulation. The inset shows normal position of the foot in the supine patient. Compare with 6.

5 The effect of the torsional and impact forces shown in 3. Note that the force D is responsible for the outward rotation of the thigh, foot and leg as represented by the characteristic position of the foot 2 as compared with the normal position 1. Note that the shortening is caused by the forces A, B and C. The dotted outline represents the normal position of the head. The impaction is principally inferior and posterior. Note that the muscular forces C tend to increase *coxa vara*. Compare with similar tendency in the normal (4) and the effect of these forces in presence of *coxa vara* (5).

6 Position which may be reached by fragments in extreme angulation due to torsional forces. This is not uncommon. Note the circular appearance of the leg when viewed from in front referred to in Figure 362. A2-E2 and A3-F3 and of much importance in the planning of reduction. The head may look posteriorly with its articular face instead of anteriorly as here shown.

and of angulation in the horizontal plane with the angle opening backward (Fig 361, 4 and 5).

If the torsional force is extreme the fragments assume the position shown in figure 361 G, not only with no impaction but with out contact of the fractured surfaces.

It is well to realize that this is not of infrequent occurrence and that the reduction maneuvers will fail to secure apposition of fractured surfaces unless modified to meet this situation.

This is an extremely unfortunate complication particularly if not recognized and modifies tremendously both the prognosis and the treatment. Unfortunately it can be revealed only by roentgenographic changes some weeks after injury, but the possibility must always be kept in mind.

Many so called intracapsular fractures of the neck are fortunately sufficiently oblique so that at least part of the fracture line particularly below and behind lies below the point of capsular reflection in the region

designated D in figure 360 II thus insuring some degree of circulation to the proximal fragment. Recognition of this fact is a matter of import in prognosis and in treatment.

For the general features of the healing process the reader is referred to the section on repair of fractures. It is desired to call attention here merely to the extraordinary features in the process which manifest themselves in this region characterized by universally slow union and all too frequent non union. The paucity of circulation for nutritive and biochemical transformation purposes and of vascular soft parts available for the growth of granulation tissue to form the basis of callus even when reduction and fixation are adequately carried out is the factor responsible. The present day attack on the problem is centered on these anatomical and pathologic features and what is most needed for improvement in general results is adequate carrying out of efficient closed or conservative methods in general hands. To the closed methods there has been added as a relatively conservative procedure that of closed reduction followed by internal fixation applied through an incision which exposes only the lateral trochanteric region. This will be described in the section on operative treatment. Open reduction at present should be definitely limited to selected cases in selected hands and under restricted conditions with the realization that open reduction of the femoral neck is at present not generally justified. This point will be further elaborated under the discussion of operative treatment.

Roentgenography—One of the difficulties in securing results in intracapsular fractures of the femoral neck by closed methods has been engendered by inadequate roentgenography. As has been pointed out in the description of the pathology of this lesion the position of the fragments determines the details of the reduction procedure and with certain rather frequent displacements the routine procedures cannot possibly result in reduction unless modified to meet the condition revealed by the roentgenograms. It is often extremely difficult to define the position of the fragments in a flat plate accurately enough to be of any practical value. The points of paramount im-

portance to the analysis of position as shown in flat plates are illustrated in figure 362 A¹—E¹ A° E. The use of stereoscopic plates naturally makes the determination of position an easier matter but they may be misleading unless accurate note of the points mentioned in the discussion of flat plates is made.

The introduction of methods allowing the taking of more or less lateral views of the femoral neck has made it possible by combining anteroposterior stereoscopic plates and a lateral view to obtain a more accurate idea of the relationship of fragments and therefore to use reduction procedures intelligently and more successfully. The value of lateral plates is briefly shown in figure 362 A² E². These lateral views can be secured without untoward difficulty. Two simple methods are those developed by George and Leonard and by Manfredi and Darrach. The former involves employment of a special curved cassette and is illustrated in figure 363 1. The latter makes use of an ordinary cassette and is illustrated in figure 363 2. Discussion of the roentgenographic check following reduction is best combined with discussion of the reduction itself since it is an indispensable part of that procedure. The roentgenographic checks revealing the progress of the healing process changes of position with or without evidence of absorptive changes and the occurrence of aseptic necrosis are all vitally concerned in treatment and will be presented under that heading.

Too much emphasis cannot be placed on the adequate roentgenography of fracture of the femoral neck with careful study and adequate interpretation thereof both before and after reduction.

There can be no question but that many of the cases of non union which help to make the care of intracapsular fractures the problem which it is result from inadequate knowledge of the position before attempted reduction resultant failure to secure adequate reduction and failure to recognize inadequate reduction in subsequent roentgenograms. The problem of union in the femoral fractures is complicated enough at the best without these added barriers to success.

Etiology—These fractures occur ordinarily in elderly persons and more frequently in women. The greater tendency to fracture

in these persons has been laid to decalcification of the bone secondary to changes due to age and decreasing bodily activity. Re-

stituents of the bone. This would make for a clearer understanding of the "brittleness". This, plus the fact that the neck of the

Fig 362—A¹, Normal hip in neutral position. Head outline is semicircular. Compare direction of first portion of lower margin of neck with D¹ (abduction) and E¹ (adduction). Moderately prominent lesser trochanter slight shortening of neck and slight broadening of greater trochanter. Compare position of articular margin of head in acetabulum with D¹ and E¹. B¹, In internal rotation. Lesser trochanter has disappeared neck shows full length and greater trochanter is seen in sharp profile. C¹, In outward rotation. Marked prominence of lesser trochanter quadrilateral face-on view of greater trochanter marked shortening of neck head outline approaching the circular instead of the semicircular. D¹, Appearance as in C¹ but the addition of abduction has changed the direction of the first portion of lower margin of neck and caused the lower portion of the articular outline to project beyond the lower edge of acetabulum and the upper portion to withdraw into the acetabulum. E¹, Appearance as in A¹ but the addition of adduction has changed the direction of the first portion of the lower margin of the neck and caused the lower portion of the articular outline to recede within the acetabulum and the upper portion to project beyond acetabular edge. Observation of these various points in a flat plate will give some idea of the positions assumed by head fragment and neck fragment.

A², fracture through mid neck. Head fragment markedly abducted. Shaft in slight abduction and moderate external rotation. At operation the raw surface of the head lay in contact with dorsal surface of neck fragment. B², Abduction and midrotation of neck fragment. Head fragment flexed and rotated so that its raw surface looked directly forward and lay against back of neck fragment. (Compare Fig 361.) C², Abduction and marked flexion of head fragment. Outward rotation and forward displacement of neck fragment (proved at operation). D², Moderate abduction of head. Neck fragment rotated outward and displaced forward (proved at operation). E², Note adduction of head moderate external rotation of neck. Stereo shows overlapping to be on different planes and not due to impaction.

Lateral views taken by Manfredi technique. B³ is the only one showing good apposition. All five looked satisfactory by ordinary flat plate standards. A³ shows forward angulation with resultant gap. C³ shows forward angulation and rotation. D³ and E³ show anteroposterior angulation and rotation. (After Darrach and Stimson.)

cent investigations tend to show however, that in addition to the decalcification there is also a marked decrease in the organic con-

femur is subjected to cross strain and to torsional strain intensified by the momentum of the body weight, readily explains

the frequency of the fracture in the aged in common with Colles fracture and the mildness of the trauma which frequently causes it

The fracturing violence is of two types and the recognition of the violence involved is of importance in treatment and prognosis

One type is that embodied in a misstep on the stairs or in stepping from a street curb or a slip on a rug or a polished floor. As a result there occurs a sudden precipitation of body weight on the affected limb with

the majority of cases the fall on the trochanter follows the fracture and is not an etiological factor

The brittle quality of these bones makes it possible for fracture to occur with a minimum of violence and any complaint of hip pain following even the mildest trauma in an elderly person places on the doctor the burden of proving that there is *not* a fracture of the femoral neck even though the patient can walk and has no demonstrable deformity

Fig. 363—1 Lateral x-rays using curved cassette (George and Leonard). Patient supine. Marked abduction not necessary. A Target of tube, above iliac crest. B curved cassette in perineum closely applied to curve of the neck. This method has the disadvantages compared with the Manfred method, of requiring a special cassette and of producing probably more distortion.

2 The Manfredi technique for lateral views. The patient lies supine with legs abducted and cassette is pushed in over iliac crest and beneath costal margin. The tube is close to the bed near the patient's opposite foot.

cross strain on the femoral neck and practically invariably a twisting effort at recovery with a coincident torsional strain (Fig. 361 4). The resultant deformities are illustrated in figure 361 5 and 6. The other type is that in which there is actually a blow against the greater trochanter without cross strain or torsion producing some impaction with a tendency to coxa valga and a minimum of soft part *viz.* circulatory damage (Fig. 361 3).

The patient will almost invariably give a history of having undergone this second type of violence—a fall on the hip—but in

Diagnosis—For purposes of discussion the fractures of the upper extremity of the femur are commonly divided as follows:

1 Intracapsular—subcapital—through the neck.

2 Extracapsular—base of the neck.

3 Intertrochanteric—peritrochanteric.

These groups often present indistinguishable pictures as far as symptoms and signs are concerned. It is best perhaps to present first the classical picture of these fractures and then the variations which may be encountered.

The patient has

misstep following a stumble or has been hit by a moving object, such as an automobile. Coincidentally there has been pain in the hip or groin and inability to use or to stand on the affected leg. When the patient is examined in the supine position, it is noted that the foot on the painful side is outwardly rotated, sometimes to such an extent that its lateral aspect lies flat on the table or bed (Fig 361, 5). Any movement of the leg causes pain in the hip or groin, more particularly abduction or internal rotation, the

have the thighs in the same degree of rotation and of abduction. The importance of these points should be obvious, as should also be the fact that it is necessary to put the sound leg in the position assumed by the injured one. The measurements are made from the anterior superior spine to either the internal or the external malleolar tip. Measurements may be exceedingly misleading unless made exactly.

Nélaton's line is a line passing from the anterior superior spine of the ilium to the

Fig 364—1, Nélaton's line. A, Anterior superior spine of ilium, B, tuberosity of ischium palpated in buttock, C, tip of greater trochanter. It can be readily seen that in coxa vara or in upward riding of the neck, the trochanter is elevated above this line.

2, Bryant's triangle. The heavy lines represent the normal. The light lines represent the condition in fracture with shortening. AB, Perpendicular from anterior superior spine to the table or bed, AC, line drawn from anterior superior spine through tip of normal greater trochanter to table, defining distance CB, normal base; AD, line drawn from anterior superior spine through tip of great trochanter elevated owing to coxa vara or upward riding of neck on head, defining DB, shortened base in this condition. The value of this determination lies in the fact that it translates a small difference in level of the great trochanters into a larger and more definitely determined base line difference.

latter being practically impossible. Inspection alone may show that the affected leg is shorter than the sound one. If this is not apparent to the eye, actual measurement plus comparison of Nélaton's line and Bryant's triangle on the two sides will reveal a varying degree of shortening.

In order to make measurement of any value it is essential to have the two anterior superior spines of the ilium on the same level, to have the hips and knees in the same degrees of flexion on the two sides and to

ischial tuberosity, with the hip in 40 degrees of flexion and in the mid-position without abduction or adduction. Such a line in such a position of the patient will pass through the tip of the greater trochanter on the sound side, but distal to it on the injured side if there has been shortening due to femoral neck fracture (Fig. 364, 1). Bryant's triangle is pictured in figure 364, 2, and presents a shortened base of the triangle as a result of shortening of the extremity due to injury of the femoral neck. In addition to

these signs the hip on the affected side is apt to be definitely more prominent than the hip on the sound side

With such a picture it should be impossible to miss the diagnosis. When however the visible outward rotation is slight and the shortening is not marked particularly when impaction sufficient to provide some degree of fixation is present the diagnosis will be frequently missed unless the measurement is carefully made of Nelaton's line and Bryant's triangle is accurately gauged. In these doubtful cases and in those presenting no gross deformity the presence of pain on attempted abduction or internal rotation eliciting of pain in the groin by a sharp blow of the closed fist on the heel of the extended leg or over the trochanter and direct tenderness in the groin are of significance. In the presence of any of these signs the case should be handled as a fracture of the femoral neck until adequate roentgen examination can settle the question. This viewpoint is important in that patients having impacted or non-displaced fractures may actually be able to walk about with only slight discomfort.

In the elderly unconscious patient following accident the hips should always be carefully examined for the possibility of fracture and if the gross signs are not present muscle spasm on movement and/or restriction of motion range particularly abduction and internal rotation should make adequate roentgen examination essential in order to rule out the possibility of fracture.

In testing rotation of the thigh it is important to grasp the knee and thigh and to gauge the movement by the position of the patella. Rotation of the foot is not an adequate gauge of hip motion because of the great amount of movement possible in the subtalar joints.

Treatment—In the treatment of these cases the fact that the patient is often aged and suffering from ailments common to old age is frequently allowed to exercise too great an influence in the choice of method. Every patient of course requires a careful and complete physical evaluation but the finding of cardiac lesions, of chronic bronchitis and emphysema, of nephritis or of vascular lesions does not mean *ipso facto* that inefficient treatment or no treatment is in-

dicated. It means merely that these lesions must be treated in addition to not to the exclusion of the fracture. Those instances in which a fatal outcome can be assumed to be the result of adequate treatment of the fracture when combined with adequate treatment and nursing of the patient are few and far between. Most of such patients face under the same type of general care just as great risk of mortality with rest in bed and sand bags or with traction suspension as they do under properly nursed plaster immobilization. If the care and supervision of the patient cannot be adequately carried out the mortality will be high in either instance. If it can be adequately carried out the mortality will be lower in those cases in which the fracture is adequately cared for. The idea that reduction of the fracture and proper immobilization after reduction have been the fatal element in these cases has been a tremendous handicap to the general adoption of adequate methods.

It is also to be kept in mind that paradoxical as it may seem at first glance the worse the general condition of the patient, the more vital the necessity for internal fixation just as soon after injury as possible with active mobilization of the patient as a whole thereafter.

Emergency Treatment—The use of the Thomas type of splint with fixed traction as advocated by the Fracture Committee of the American College of Surgeons is a temporary immobilization pending definite treatment of extreme value in these cases. While it does not immobilize the hip joint, it keeps the fragments adequately fixed and prevents further deformity and damage by the maintenance of constant traction. It should be applied as soon as the diagnosis of fracture or suspected fracture is made and kept on during the transportation to the hospital and to and from the x-ray room and during preliminary treatment of the patient until definite treatment is undertaken.

If a Thomas type of splint is not available then a long Liston board splint from the axilla to beyond the foot should be applied but it is infinitely less effective. In an emergency the two legs and the hip can be bandaged together, the sound side acting somewhat as a splint for the injured one. Numerous numerous methods of applying traction without the use of the Thomas (Keller-Blake) type of splint have been devised. The reader is referred to the section on the emergency treatment and transportation of patients with fractures for the details.

If the patient is in shock it should be combated by the recognized methods. Since the trauma involved in the average case is relatively mild shock is not present. However with the Thomas splint

a procedure which takes less than five minutes and which should be devoid of pain or discomfort or added shock to the patient as much time as is needed may be safely taken for the treatment.

Since the patient is usually aged and subject to the general diseases of old individuals of the age group it is essential to evaluate his condition thoroughly before the treatment of the fracture is started in order that whatever disease he may be suffering from can be adequately cared for concurrently with the fracture. Emphysema and chronic bronchitis, arterial sclerosis (generalized cerebral or renal), hypertension, renal disease, cancer disease and diabetes are among the problems presenting themselves. It should be distinctly understood that probably none of these conditions has any effect on the healing of the fracture. Their effect is apparent principally in the mortality rate. Nor is any one of them more than a temporary bar to the adequate treatment of the fracture unless the patient is fractally moribund. But the accurate determination of the presence or absence is of vital importance in planning the treatment the patient must have in connection with the treatment of his fracture. It is false to carry out the primary careful evaluation of the patient which is responsible for the growth as an impaction of a plaster cast is an important element in the mortality rate of the fracture. It is also to be remembered that it is wise to delay internal fixation if it is to be used for days in order to make the evaluation. Some hours of delay for the treatment of real shock is justified but three or four days rest in bed before operation is definitely more of a handicap than a help.

Following the application of the Thomas type of splint the treatment of whatever shock may be present, the taking of a leguete roentgenographic a temporary or preferably stereoscopic and lateral views and the careful evaluation of the patient as a whole the patient and his fracture can then be treated intelligently.

Reduction—This may be accomplished by a closed or an open method. As previously stated open reduction should be reserved for special writing for selected cases in special hands. The method of choice for the average surgeon is the closed method preferably followed by internal fixation applied through an incision over the lateral trochanteric region.

Any one of a variety of anesthetics may be employed. Local anesthesia (injection of novocain into the hematoma about the fracture) may be excellent if the reduction can be done within a few hours after the injury. Gas oxygen with or without barbiturates (from 60 to 80 mg per kilo) is usually very satisfactory. Spinal anesthesia particularly with the use of pontocaine which prolongs the anesthesia for two or three hours may be very successfully used.

To avoid the large drop in blood pressure that frequently occurs with spinal anesthesia particularly in cases of hypertension unilateral anesthesia can be secured by employing a heavy specific gravity pontocaine and a special technique. In patients showing but slight displacement and requiring but little manipulation a large dose of morphine or rectal paraldehyde may be quite adequate.

Closed reduction is best accomplished by either of two methods. The first is that of Whitman slightly modified in view of more accurate present day knowledge as to the position of fragments gained as the result of stereoscopic and lateral roentgen studies (Fig 360 1-4). The modification consists in the application of outward traction to the thigh preceding and accompanying the downward traction with the object of disengaging the fragments preliminary to placing them in their proper relationships. In addition to accomplishing this the maneuver is practically essential when the deformity is that represented in figure 361 c in order to remove the pressure of the neck from the head fragment so that the latter may drop back or come forward as the case may be to the position where it is possible to get the broken surfaces in contact.

The second method is that of Leadbetter (Fig 365 5 and 6). The flexion of the hip in this instance secures relaxation of the muscles about the joint thereby having the same effect as the outward traction in the Whitman method since it relieves muscular tension and spasm which maintain pressure of the neck against the head fragment.

A matter of importance in the reduction is that one strives to attain not anatomical reposition but actual *covax* of mild degree. It is in effect a slight overcorrection of the deformity in order that the normal forces of the muscles running between the pelvis and the thigh and the impact of weight bearing shall both tend to force the fragments more tightly together in place of exerting a shearing strain at the fracture site with tendency to produce *covax* as is the case in the normal femoral neck (Fig 361). The importance of this overcorrection has been increasingly appreciated within the last few years and a satisfactory reduction is to be considered one in which slight *covax* position has been attained rather than

one in which normal anatomy has resulted progression of coxa vara deformity on
This elimination of a shearing strain is of weight bearing which is often seen after the

Fig 365—The Whitman reduction (modified) 1 A Traction downward on legs against counter traction B in perineum (post in table or rolled sheet passed through perineum and fastened to head of table) concurrent traction C (against crest of ilium—manual or by swathe around thigh and operator's waist) against counter traction O (against crest of ilium—manual or by sheet fastened to opposite side of table) O disengages the fragments and A should restore normal length SS the anterior superior spines must be kept on same level at all times P the patellae both look directly anteriorly and the feet point anteriorly

2 A B O and C continued Thigh just above the knee is rotated (R) inward strongly Patella now looks inward on treated side foot points inward correspondingly No strain on knee or ankle It is wrong and harmful to perform this rotation using the leg or the foot as a lever since the knee or ankle and knee are then under strain and are apt to be uncomfortable and to stiffen up immoderately in plaster

3 O and C released A and B maintained and both legs carried out to full physiological abduction as far as by limit of sound side Inversion of injured side maintained

4 Injured side carried a little beyond normal abduction limit to secure mild coxa valga, and impaction, and into mild hyperextension

5 and 6 Leadbetter method of reduction The patient lies supine on the table 5 The anterior superior spines (S) are held firmly down (manually by an assistant or by a swathe passed underneath the table C) The operator places the patient's feet and with his shoulder underneath the calf at A as a fulcrum and upward push and his two hands over the front of the leg at B exerting a downward leverage secures powerful traction in the longitudinal axis of the femur The flexion relaxes the musculature about the hip joint and thereby relieves the tension which is holding the displaced fragments tightly together in addition by the exerting of lateral leverage during the procedure the fragments can be actually pulled apart (Compare lever O in Whitman method modified)

6 Traction and lateral leverage maintained while the leg is swung outward sharply (D) causing corresponding inward rotation of thigh (E) to point of resistance The inverted and flexed thigh is then brought down into full extension and abduction as one movement (F) The degree of abduction should then be increased to slightly beyond normal limit as gauged by normal side to secure slight coxa valga position Movements D and F should be sharply done as they have for their purpose not only correction of deformity (outward rotation of shaft and coxa vara respectively) but impaction in the corrected position as well

extreme importance in aiding the maintenance of position and in obviating the slow healing of an anatomical replacement has been satisfactory

Following the reduction by either method, with the leg held in the position in which it is to be immobilized, mensuration and the so-called Leadbetter test for adequate reduction are made. Measurements between the anterior superior spines and the tips of the internal malleoli on the two sides determine whether or not all shortening has been corrected. The Leadbetter test consists in resting the heel of the foot of the affected

These two seem to be the most acceptable. Operative treatment will be briefly discussed after the closed treatment has been fully considered.

Immobilization—This is ordinarily accomplished by the use of the plaster spica, of which there are two types (Fig 366). The Whitman spica immobilizes the pelvis by making it continuous with the chest wall, therefore preventing tilting away from the

Fig 366—Two types of plaster spica. *A*, Whitman spica. Includes both anterior superior spines, the thorax to the axilla, and the affected leg to the toes. The normal leg is completely free. The affected leg is in slightly beyond normal abduction, inverted so that the patella looks inward and upward at an angle of about 40 to 45 degrees, and the hip is in slight hyperextension. This hyperextension makes it necessary to have the plaster-encased leg extend beyond the edge of the bed (*a*) as shown. The knee is in very slight flexion. If reduction has been properly carried out there should be no strain on the knee or ankle in plaster. The chest portion of the spica is essential to prevent tilting of the pelvis with loss of abduction.

B, Double spica designed to immobilize hip adequately without limiting chest movements and allowing some degree of waist flexion for semi-sitting etc. The normal leg is in full abduction, the affected one in the same position as the Whitman. The pelvis is fixed by the double abduction so preventing tilting with loss of abduction. A cross bar incorporated in the plaster safeguards rigidity and aids in nursing (lifting, turning etc.). The sound leg has a free knee, leg and foot. The advantages of this over the Whitman are highly theoretical under adequate nursing. If nursing care is sketchy it is probably preferable. Under adequate care, it is not as desirable. (See text.) Either spica may be put on over stockinet with felt pad protection for bony points, or cotton wadding padding. The former is probably preferable. (See text.)

side on the flat palm of the operator's hand without other support. If the torsional deformity has been adequately corrected and if the fragments are locked in the corrected position, the foot will remain upright. If either correction or locking is deficient, the foot will roll into the outward rotation characteristic of fracture of the femoral neck. The test is very definitely worth while.

Other methods of closed reduction are described and will be briefly referred to later

affected side which would produce adduction and nullify the reduction (Fig. 367). It leaves the sound leg and thigh in complete freedom but restricts the chest movements. It is mechanically extremely effective if adequately applied. The double spica has the theoretical advantage of leaving the chest movements without restriction, but it ties up the hip on the sound side and is less certain to prevent tilting of the pelvis unless both legs are in extremely wide abduction.

one in which normal anatomy has resulted in progressive
This elimination of a shearing strain is of weight b

This is a more awkward position than that secured in the Whitman spica and is I believe just as uncomfortable for the patient.

If there should be real pulmonary threats in the way of severe bronchitis (acute or chronic) asthma or marked emphysema the double spica has a definite advantage. Otherwise the Whitman spica is probably more desirable.

It will be noted that a window is provided in the abdominal portion of the Whitman spica which allows for more freedom in abdominal respiration for comfort after eating and in the presence of slight disten-

pads under the stockinet on either side of the area to be protected but not over it. The latter method is preferable. The points to be guarded are the sacrum and vertebral spinous processes the anterior superior spines and iliac crests the anterior sharp edge of the tibia the malleoli the dorsum of the foot and the heel. Where the Whitman spica encompasses the chest wall, a wide band of felt or a double layer of buliard table cloth is of advantage.

The skin should be well dried and profusely powdered before the application of the stockinet or wadding.

Fig. 367.—Illustrating the principle of gaining abduction by tilting of the pelvis on the fixed leg instead of abducting the leg on the fixed pelvis.

Left. Normal position of pelvis and spine. Pelvis is level, anterior superior spines on same level. Legs in neutral position as regards general body axis. *AA'*, Longitudinal axis of pelvis coincides with body axis. *Coxa vara* in fractured right femoral neck.

Right. Pelvis tilted by pulling down on injured side or pushing up on sound side or both. Legs are still in neutral position as regards general body axis but actually in abduction on right and adduction on left in respect to pelvis axis *BC*, abduction on right correcting *coxa vara*.

on and for ventilation. In both spicas a window is cut over the patella in part to prevent pressure but principally so that free motion of the patella through voluntary contractions of the quadriceps can be carried out without difficulty.

In either spica the knee should be in slight extension (from 5 to 10 degrees) and the hip on the affected side in hyperextension.

Either spica should be applied with adequate protection for points of pressure. This can be accomplished by snug application of cotton wadding under the plaster or the patient may be encased in stockinet and pressure points protected by the use of soft felt

The application of a plaster spica is erroneously looked on as a simple and easy procedure. It is frequently turned over to some subordinate with little or no supervision. It is a waste of time and a positive threat to the patient unless it is accurately and relatively comfortably applied. It is frequently blamed for difficulties which are due purely to the lack of care or skill in its application. If one is going to treat these fractures successfully one must know how to apply a spica properly and must see that it is so applied.

Course and Nursing.—The course in these cases is to be sure prolonged. It is

the rare case in which there is adequate healing by the end of eight weeks although the idea that the spica should routinely be removed at that time is quite prevalent. It is usually from twelve to sixteen weeks and frequently longer before it is safe to remove it even when healing has been progressing satisfactorily. It has been said that if all patients were kept in plaster adequately reduced and immobilized for from six months to a year there would be about 90 per cent of bony unions in the survivors of the ordeal. The mortality would of course be tremendous and prohibitive but the principle involved is sound. The problem really resolves itself into maintaining accurate position and immobilization for a long enough time and devoting further efforts to guarding against the Damoclean sword of threatened mortality. These efforts comprise an adequate care of any intercurrent or coincident disease as would be given were the patient not suffering from a fracture and attention to the patient's general state of health.

The majority of the fatal issues may be grouped under two heads—one group comprising the pulmonary complications (so called hypostatic congestions and pneumonias, pulmonary emboli and pulmonary infarctions due to intrapulmonary thrombosis followed by pneumonitis) and a second group characterized by cerebral symptoms and increasing general debility with disorientation, mental apathy and deterioration slowly passing into stupor, coma and death. The first group are commonly combined under the term hypostatic pneumonias but are with the exception of the clear cut embolism cases probably for the greater part intrapulmonary thrombosis with infarctions of the lung and secondary pneumonitis. There is no more to be done at present for the embolism cases than is done to prevent embolism in the course of surgical conditions in general. They occur as frequently in non-immobilized patients as they do in the immobilized ones. Whether the other lung complications are hypostatic or thrombotic is of academic interest. The point of importance is that in either instance they are the result of circulatory factors. These patients are in general elderly with a minimal circulatory efficiency efficient largely because of their muscular activity in their daily life.

Following injury whether they be in plaster or between sand bags if they are kept still in bed their circulatory activity approaches the stagnation point. Positional or hypostatic congestion with edema may then occur—in subcutaneous tissues as well as in pulmonary tissue. Thrombosis in venous channels apparently requires the double factor of relative circulatory stasis and some factor as yet not clearly defined leading to increased tendency to blood coagulation in the patient. Studies by Bancroft and his associates have revealed many interesting facts in this connection. In those bedridden patients in whom this factor is present thrombosis may occur. In either instance the indication is clear—frequent positional change and as much muscular activity as possible.

The frequent positional change can be secured with either spica by turning the patient face downward at least twice daily for one-half to three quarter hour periods by raising and lowering at intervals during the day the head portion of the bed on blocks with the Whitman spica or the head gatch in the short wisted double spica.

The combating of circulatory stasis is accomplished by putting a trapeze over the head of the patient and making him aid in his positional changes by enforcing frequent routine exercise of the upper extremities and of whatever portion of the lower extremities is free. Quadriceps contraction with patellar movements and toe exercises can be carried out on the injured side. Occupational therapy of some sort for these bedridden patients is a great help. The importance of these aids to circulatory activity cannot be overestimated. To allow an aged patient to vegetate passively in bed is to ask for trouble particularly after tissue damage which seems connected with the presence of or increase in the factor favoring coagulation of the blood.

The cases characterized by cerebral symptoms and gradual drifting out of the patient are probably similarly due to circulatory stasis and progressive cerebral thrombosis and can best be guarded against by a similar routine. A certain percentage of these cases are probably instances of fat embolism.

In patients showing the tendency to hypostatic congestion or cerebral symptoms despite the type of care just outlined the

administration of sodium thiosulfate (1 Gm in 10 cc of saline solution intravenously every other day for three or four doses repeated at intervals with a week between each series of injections) seems empirically to lessen the tendency in some cases strikingly so. The mechanism of its action is far from clearly understood although it is presumably concerned with lessening the facility of blood coagulation. In a wide acquaintance with its use and action I have never seen any untoward results follow its administration nor do I know of any in the experience of others. And while its use is purely empirical it produces apparent results in a high enough percentage of cases to make it clearly worth while.

Next in importance to attention to the patient's circulatory status comes care of the skin. The skin must be kept clean and dry. That means cleansing with soap and water then thorough removal of the soap followed by the use of alcohol and some form of drying powder used lavishly. It also means frequent slight changes in position in addition to the turning of the patient and protection from all plaster edges by adequate binding of the latter. Powder should also be kept sifted down through all the apertures in the spacer to keep the skin beneath as dry as possible. If redness of the skin appears at any point exposure to dry heat protection by soft felt around but not over that point and frequent powdering will avoid progression to actual ulceration. Frequently skin complications develop because the plaster is so applied that the patient is constantly uncomfortable and keeps trying to shift around inside the spacer with resultant rubbing.

Apart from these nursing problems the care of the patient resolves itself into observation and treatment of the fracture. Roentgenographic observation subject to the same comments as made previously should be made weekly. This is for two reasons—first for evidence of aseptic necrosis partial or complete of the head and second for absorption at the fracture site with resultant loss of position. This latter occurs in about 90 per cent of cases. The former depends on the amount of circulatory damage sustained at the time of injury or due to secondary thromboses. In the first event it means a prolonged period of immobilization or re-

course to operative measures. In the second instance it means a change of plaster with regaining of the lost position. It is a vital mistake to remove plaster indiscriminately and routinely at the end of eight weeks and to decide that non union is inevitable and has in fact occurred. If there has been no evidence of either necrosis or absorption the best plan is to bivalve the plaster at the end of eight weeks have the patient lifted out and a roentgenogram made while the position is manually maintained and the bivalved plaster replaced until the films are seen. If as is the case in the minority of successful cases position and healing are satisfactory the plaster can be removed. If not either a new spacer is applied in accurate position and kept on for four weeks before another similar cast or else some other form of treatment open or closed is substituted. Many patients with adequate plaster and adequate nursing can be kept in the cast if need be for from twenty to twenty-four weeks.

Assuming that the treatment has been successful and that the cast has been removed at from eight to twenty-four weeks with roentgen evidence of satisfactory healing the patient is given massage to the calf and thigh muscles heat—either by lamp or diathermy—and if possible some muscle stimulation using the Smart coil or sinusoidal current and the leg gradually brought into adduction. Active motions within pain limits of knee ankle and hip are instituted—short periods frequently repeated (such as from three to five minutes every hour). These can be passively aided by a loop of bandage beneath the sole of the patient's foot on which he can pull to aid dorsiflexion and a sling under his knee with the rope through an overhead pulley to his hand with which he can aid flexion of the knee and hip. By the end of a week he is in a wheel chair and a walking caliper can be applied (Fig. 369). He then starts standing and soon walks with crutch support substituting a cane if and when possible. It is important to check the caliper carefully to see that it fulfill the conditions noted in the figure. The periods of standing and walking should again be short but frequently repeated. When the upright position is first assumed it is of great advantage to bandage the patient's

legs to the knees with an Ace or some other elastic bandage and to maintain this passive circulatory support for a period of some months to minimize swelling when the legs

1 monthly roentgen check is made for evidence of maintenance of position and progress of healing. Healing progress is denoted by decreasing clarity in the line of fracture,

Fig. 368—Caliper splints. The illustration shows a well-designed caliper. The ring open anteriorly is slanted so as to come beneath the anterior superior spine at A but above the level of the trochanter tip and to escape impact on the pubic bone (D) at B by at least 2 fingerbreadths when the patient's weight is resting on the splint. It is indented at C so as to dip in under the tuberosity. When patient's weight is on the splint, it should be impossible to get the finger between the tuberosity and the ring. A knee joint with a lock that can be controlled by the patient through his clothes should be exactly at the knee joint axis of motion. The leg is held in the splint either by laced leather cuffs as shown or by straps in front with circular flat metal bands incorporated in the splint behind. The foot end of the splint is fastened into sockets in the heel of the shoe or may be fitted with an ankle joint as shown in G, the lower end being riveted to the instep of the shoe. The proper length is such that when the patient's weight is on the brace, the heel just rests on the shoe and the ring is tight against the tuberosity. If too long the heel tends to pull out of the shoe. If too short the tuberosity does not rest on the ring and the neck can shorten until it does. The upper ring may be made closed but the anterior portion tends to interfere with sitting. The knee joint is flexed in sitting and locked in extension in weight bearing. When the non weight bearing type of caliper is desired it is made longer than the leg and terminated in a rubber-covered bar (H). By means of buckles on the sides of the shoe and straps attached to the end of the brace moderate traction can be maintained. A raised sole and heel is worn on the other shoe. These points are important. Many well reduced and primarily healed fractures lose position gradually on braces which do not support because they do not fulfill the requirements indicated.

are dependent. As soon as the patient can be helped into a tub under water exercise for knee, hip and ankle is of great help. A pool of course is better still. Progressive exercise and ambulation are practiced and

increasing density of bone and the presence of trabeculations crossing the fracture line. It is only when this trabeculation is quite apparent across the fracture region, after the fracture line has lost its identity, that

brace support should be removed and walking without the brace at first with crutches within a week or two with a cane and as soon as possible without a cane should be instituted. The period of brace support varies of course. It usually runs between four and six months at a minimum and may be needed for a year as indicated by the roentgen check. Crutches without actual weight bearing on the affected leg may be used instead but with the obvious disadvantage that without actual weight bearing the callus or granizes much more slowly and trabeculation is apt to be delayed. The purpose of the brace is to allow weight bearing but to prevent shortening by collapse of the unorganized callus. Many surgeons prefer to substitute for the caliper brace period a similar period of walking with crutches without bearing weight on the affected leg. For a reliable and trustworthy patient, this is probably preferable to the brace.

Other Closed Methods—The reduction of the fracture in whole or in part has been varied by the use of mechanical aids and the fixation has been varied with the idea of allowing freedom of motion at the hip during the period of fixation.

The Ruth method of reduction employs the same mechanism on the flexed thigh as previously described under the Leadbetter procedure except that it is not a "one man job" in that outward traction on the thigh is exercised by an assistant (as in the modified Whitman method) and the force exerted on the leg is made by a second assistant. The mechanism is essentially the same. The reduction is followed by the application of a short double spica as described in figure 366 except that the sound leg is included to the ankle and that a period of three weeks between reduction and immobilization is allowed with the patient in traction in bilateral wide abduction with a lateral pull by a sling around the thigh. There seems to be little if any advantageous reason for this intervening period.

The Wilkie procedure is essentially one of immobilization and must be preceded by adequate reduction. Its chief feature is immobilization by full bilateral abduction in version maintained by two leg boots of plaster and a cross bar (roomstick) at the feet or ankles. It allows the patient to sit up

that is as much and as comfortably as wide bilateral abduction and straight knee will permit and is designed principally for ease of application and for its effect on the mortality factors. The rigidity of fixation is somewhat questionable and if any absorption occurs it is precarious. The knee strain if abduction is fully maintained is considerable. It can be used if adequate spica immobilization is impossible for any good reason (soft part damage, lack of facilities, lack of ability, patient's refusal) but is essentially a much less efficient substitute.

Two common methods in use depend for the abduction and traction phases of reduction on tilting of the pelvis (Fig. 367) employing the well leg traction principle of Hoke. In one the Carl Jones splint is used. In the other the Roger Anderson splint is used. In each instance pull downward is exercised on the injured leg and push upward on the sound leg thereby tilting the pelvis. As the use of these methods is not advocated in fractures of the femoral neck of the intracapsular type their description is deferred to the discussion of the intertrochanteric and base of the neck fractures to which they are applicable.

In those who are essentially bedridden before the time of accident or who are so aged and senile that it is felt that they would never walk again even if a satisfactory healing of the fracture were secured there seems an logical reason for carrying out the arduous course of closed reduction and immobilization. The indication in these cases if it has been decided that internal fixation is contraindicated by reason of lack of facilities or by reason of the patient's condition is to make the patient comfortable during the period of pain and spasm. When he can be in bed or sit in a chair and undergo the usual care with no discomfort from the hip the treatment has fulfilled its purpose. The idea of this type of treatment is not carried out by sand bag immobilization. It is best carried out by balanced traction suspension until such time as the patient is comfortable without it. Adequately applied it will keep the patient comfortable and will greatly simplify nursing. Neither of these statements is true of sand bag treatment. The method is described under the treatment of the following group (intertrochanteric frac-

tures). It is, of course, only under those circumstances where the relatively conservative procedure of closed reduction followed by internal fixation through an incision along the lateral trochanteric region cannot be used, for one reason or another, that purely closed methods with immobilization are today justified and that the above advice as to the bedridden and senile patient holds good.

If, following adequate reduction and maintenance of reduction for the prolonged period indicated, non-union with or without

terion on which to base a decision. Many patients with absolute non-union, even with absorption, showing 1 to 2½ inches of shortening, and with marked limp may obtain a practically painless condition of the hip with a satisfactory range of motion under either of the two methods first mentioned. Before deciding between the conservative and the operative handling of these "x-ray failures," one must consider the patient as an operative risk, his temperament, his economic status, the quality of surgery which is available for him, and the question of what will

Fig. 369.—Patient in thigh and leg skin traction in Thomas splint and Pearson leg piece. Compare with figures 373, 376, and 377 for diagram of details.

absorption has occurred, or if, because of one factor or another, it has been impossible to carry out treatment and non-union is the result in a patient who has to be up and about, a decision must be made as to the proper treatment. Long-continued non-weight-bearing traction brace support (Fig. 368), long-continued crutch support with initial slight but gradually increasing weight bearing, operative reduction and internal fixation by one means or another, and an operative reconstruction procedure are the alternatives which present themselves. The roentgenogram should not be the sole cri-

terion on which to base a decision. Many patients with absolute non-union, even with absorption, showing 1 to 2½ inches of shortening, and with marked limp may obtain a practically painless condition of the hip with a satisfactory range of motion under either of the two methods first mentioned. Before deciding between the conservative and the operative handling of these "x-ray failures," one must consider the patient as an operative risk, his temperament, his economic status, the quality of surgery which is available for him, and the question of what will

Operative Treatment.—Operative treatment of an intracapsular fracture must be considered under two heads—that of the

primary operative treatment of the fresh fracture and that of the late operative handling of the ununited or malunited fracture

Primary Operative Treatment—Many methods for the primary operative treatment in these cases have been developed. I have included in this class all procedures which are accompanied by actual operation. Some of them combine closed reduction for the fracture itself with open exposure of the trochanter for purposes of fixation or of providing circulation or both. Some of them call for postoperative immobilization as in the purely closed methods. Others allow of early mobilization of the extremity or early mobilization of the patient or both. In order to evaluate adequately the various methods in use it might be wise to look into the justification for operative methods. The matter may be regarded from three viewpoints—that of mortality, that of bony union and that of function of the extremity.

Mortality—Elderly patients with intracapsular fracture die because of being kept quiet and immobilized in bed; the resulting circulatory stasis leading to various fatal complications, pulmonary and cerebral. To be fully efficient operative treatment must allow mobilization of the extremity as well as of the patient. There is no question but that the mortality is lowered and lowered tremendously if this can be done, provided the operation as done does not add a mortality rate of its own.

Bony Union—If the prospects of bony union are to be enhanced, the improved chance must not be gained at the expense of an increased mortality. Increased chance of bony union results from more accurate reduction from prolonged immobilization of the fracture site and from rapidity of restoration of circulation lost by reason of the trauma. To be fully efficient on this score operative treatment must provide accurate reduction, prolonged immobilization of the fracture site and opportunities for restoration of circulatory loss without immobilizing the extremity or the patient.

Function of the Extremity—Joint function, muscle strength and bony anatomy are the three factors involved in the function of the lower extremity. Mobilization of the joints, development of muscle power and ac-

curate restoration of bony anatomy are demanded of operative treatment if it is to be fully efficient.

On the basis of these three criteria the open methods used as the primary treatment of the fresh fracture will be discussed and evaluated.

1 OPEN REDUCTION OF THE FRACTURE—Developed largely through the efforts of Smith Petersen of Boston, this procedure has taught us a great deal about fractures of the femoral neck. Indeed, I believe that Smith Petersen's influence in developing sound treatment of this fracture ranks with that of Whitman. They represent the two outstanding influences in this field. The actual pathologic condition of the fracture site, the inadequacy of ordinary roentgenography, the mechanism of adequate reduction and the basis of rigid fixation have all been clarified and further developed on the basis of Smith Petersen's contributions.

Within the last few years this has led to a conviction that adequate reduction and fixation can be secured in the vast majority of cases without the necessity for open reduction of the fracture itself. Open reduction of these fractures is a formidable procedure that must be limited to selected cases in the hands of particularly qualified surgeons.

2 CLOSED REDUCTION WITH INTERNAL FIXATION—This is today the accepted method of primary treatment when it can be done. Reduction is accomplished by either of the methods advised in the section on closed reduction and after adequate roentgenologic check to prove the position, fixation is inserted through an incision over the lateral aspect of the trochanter without exposing the fracture. For the method to fulfill its purpose it must dispense with postreduction plaster immobilization and must allow the patient to be active first in bed and later in a chair and walking on crutches. There is no justification in getting the patient up in a chair or on crutches within a few hours or a day after the fixation unless his pulmonary or circulatory status is critical. There is nothing in particular to gain by such precipitate action except to shorten the stay in the hospital by a few days. If the patient is kept in balanced suspension in bed, moving himself about and moving the extremity in suspension for a

week to ten days and then started on chair and crutches without weight bearing on the affected leg the purpose of the treatment is fulfilled. Incidentally, it is better to use crutches and no weight bearing on the affected leg in these cases than it is to use a brace. The torsional strain occasioned by a brace before bone healing occurs is a disadvantage. A particularly feeble or unreliable patient may however require the use of a brace.

Many methods of fixation have been devised. Fixation by the flanged nail of Smith

use is that employing multiple Kirschner wires either directly through the skin or through an incision over the outer trochanteric aspect. This method is inadequate since the multiple Kirschner wires will not stand the strain of muscle pull without bending, much less the strain of active exercise. *Coxa vara* deformity and shearing strain result. Because of this multiple wires which are of more rigid construction such as those of Ransohoff and Telson have been used. The insertion of such wires is less difficult than the insertion of the Smith Petersen

Fig. 370—Common operative procedures in fracture of femoral neck. A, Smith-Petersen flanged nail. Used in conjunction with either open or closed reduction of the fracture itself. B, bone pegs. Either the double peg or a single one may be used with either open or closed reduction of the fracture itself. C, multiple drill holes from trochanter through neck, fragment into head. Usually used in conjunction with closed reduction of fracture. D, multiple Kirschner wires directly through skin or openly inserted following closed reduction. E, Whitman type of reconstruction following old ununited fracture. Head is removed, smoothed neck fragment placed in acetabulum and trochanter with its muscle attachments transplanted as indicated. F, Brackett and Magnuson type of reconstruction. Head retained followed out to form cap sitting on top of rounded-off end of neck and trochanter transplanted as indicated. Thrust is directly upward into head instead of cross strain. (Compare Fig. 361 diagrams 8, 4 and 5.)

Petersen is mechanically the most advantageous in that its three thin blades, radiating fanlike from a common center, provide fixation with a minimum of bone damage and are an effective bar to rotation of the fragments on one another, even though some absorption occurs about the pin. It is essential for the pin to be placed at an oblique angle and for the fixation to be in slight *coxa vara* position. The procedure calls for impaction of the fragments as the nail is introduced, since the driving of the nail tends to separate the fragments a little.

Another method of fixation in common

pin but I see no particular advantage in their use. However, if they are rigid enough and accurately placed and if impaction is practiced they may give adequate fixation. Penetration of the joint cavity and even of the pelvis may result unless particular care is exercised in making a roentgenographic check. The Smith-Petersen pin is generally considered as preferable.

The use of lag screws for the fixation, such as that of Henderson, has been practiced. In theory, rigid fixation and a constant pull approximating head to neck are its advantages. Since the lag screw is embedded in

the cancellous head and since it does much more damage than the Smith Petersen pin in its insertion it seems to have its theoretic advantages counterbalanced by practical disadvantages.

Bone pegs from the tibia (Albee, Wilson) or from the greater trochanter (Jones) have been used. As a primary procedure they fail to fulfill the requisite of allowing the patient and the limb to be mobilized. Their theoretic advantage lies in their possible aid to reestablishing circulation but that they do this is far from being shown. They are therefore not to be recommended for a primary procedure.

completed fixation is essential. This means that for the employment of this method of fixation a *sine qua non* includes facilities for taking adequate roentgenogram in the operating room and of seeing them at each step before proceeding to the next one.

It is impossible at present to advise the use of any one protractor or range finder or method of determining the course of the fixation. Many are in existence, and many are being developed. In general the simplest one with which results can be obtained is the best. No one of them is sufficient to eliminate the absolute necessity of roentgenographic control.

Fig. 371—Austin Moore pins. The four pins are placed so as to impinge on the neck cortex above and below. A nut on the end of each prevents further penetration. The four pins are wired together; the tension of the wire tends to prevent extrusion of the pins. The drawing at the right shows the placing of the pins in the lateral plane. Carothers, of Cincinnati, uses three somewhat similar pins of specially tempered steel, placed parallel, one at the upper border of the neck, one at the lower border and the third one midway between, all of them lying in the medial position in the lateral view. They are inserted at an oblique angle as possible with the shaft below the trochanter.

For all these methods of fixation without the use of open reduction numerous methods of protraction and range finding have been devised for accuracy in placement of nails, screws and wire. The preliminary insertion of a wire over which a perforated model of the Smith Petersen nail is to be threaded is used. It enlarges at times complications in the removal of the wire if bending occurs. No matter what protractor or range finder is used, no matter what anatomical landmarks are used and whether or not preliminary wire insertion is employed, an adequate anteroposterior and lateral roentgenographic check of the reduced fracture of the started nail, wire or screw and of the

In the author's experience following the advice of Smith Petersen, the use of a Kirschner wire passed $1\frac{1}{2}$ inches below the ridge on the greater trochanter representing the attachment of the vastus lateralis at exactly 45 degrees to the shaft of the femur midway between the anterior and posterior borders of the bone and parallel to the table (with the thigh in full extension and with 15 degrees of internal rotation) has been all the guide needed for accurate placement of a Smith Petersen nail. Roentgenograms of a wire so placed will give definite information as to just how the nail should be placed. The lateral view is of course essential. Before driving the nail in

it is well to insert the wire far enough to penetrate the acetabulum for a short distance. This serves to keep the head of the femur from shifting its position as a result of mallet blows on the nail.

One further note of warning—it has been too readily assumed that the so called closed pinning of a fractured femoral neck is a simple harmless procedure. Nothing is further from the truth. It should be done under rigid asepsis as for any other operation. And its accomplishment does not mean that the patient can bear weight any sooner with safety than he can under fully closed methods.

To summarize it may be said that at present the method of choice in the treatment of an intracapsular fracture of the femoral neck is closed reduction adequately checked roentgenographically and followed by internal fixation placed through an incision over the outer aspect of the trochanter. The simplest method found feasible for determining the direction of the pin should be used and the insertion of the fixation should be checked by anteroposterior and lateral roentgenograms at its beginning during its course and at the close of the procedure. The Smith Petersen nail still offers the most efficient mechanical method of fixation. The post reduction course should not be too assiduously rushed particularly as regards weight bearing. The procedure should be done under rigid surgical asepsis. It will allow of early mobilization of the extremity and of the patient with lowering of the mortality rate and earlier and better functional results and the results as to bony union will be enhanced by reason of the prolonged fixation of the fracture site which it makes possible.

It may well be that the drilling of multiple fine holes from the trochanter into the head (Bozsan) after the reduction and fixation may affect the chances of bony union by aiding vascular rehabilitation. It should be given adequate trial and may help to avoid the late degenerative changes which occur even when bony union has been secured. If practiced as a primary procedure after closed reduction but followed by plaster immobilization instead of internal fixation it has all the mortality and functional risks of plaster treatment.

Secondary Operative Treatment—
1 WHEN CLOSED REDUCTION AND IMMOBILIZATION HAVE FAILED AFTER A REASONABLE TIME—If the position is good but union has not occurred fixation without open reduction by means of the Smith Petersen nail combined with the use of the drilling as previously mentioned (Bozsan) may be effective.

Open reduction with the nail fixation and open reduction with use of a bone graft through the trochanter and into the head may be used the latter followed by plaster immobilization.

The same comments apply to these methods as previously made.

2 WHEN CONSERVATIVE METHODS AFTER FAILURE OF UNION HAVE BEEN UNSUCCESSFUL—The reconstruction operations described in figure 370 are indicated. If these are unsuccessful arthrodesis of the hip may be indicated if the patient can stand it. In addition to these three other procedures should be mentioned. One is the reconstruction devised by Colonna based on the Whitman reconstruction but designed to hold more adequately a smooth covered surface within the acetabulum. In this procedure the muscle attachments are removed from the greater trochanter, leaving smooth periosteum and the trochanter itself is placed in the acetabulum the detached muscles being attached to the shaft well below and serving to keep the trochanter pulled into the acetabulum. A second procedure is that used by Watson Jones of Liverpool for the old and feeble patient who may not be able to stand either reconstruction or arthrodesis. It consists in fixing both the fracture and the joint by driving a special large pin of the Smith Petersen type through a lateral incision from the trochanter through the acetabulum giving mechanical fixation capable of limited weight bearing.

Finally, in place of reconstruction or of arthrodesis a McMurray osteotomy may be performed. It will frequently relieve pain and give a good hip. Many surgeons prefer it to the rigor of reconstructive or arthrodesis procedures.

Prognosis in Intracapsular Fracture—The mortality rate with the use of closed reduction and plaster as determined by a cross section study of the country at large is

high. In individual localities it varies with the efficiency with which both the fracture and the patient are treated, with the size of the series of reported cases and with the nature of the institution and the type of patient (private clinics on the one hand and municipal and county hospitals on the other, are the two extremes). The average by and large is about 20 per cent. As low as 7 per cent has been reported (Stearns), and as high as 35 or 40 per cent is found

5 and 10 per cent. Under closed reduction with fixation through the lateral incision the mortality has been much further reduced, being reported as zero by some groups, but less than 5 per cent certainly for all. Available statistics show variations in connection with the size of the series reported, the selection of cases and the criteria used for judging results, successes (meaning satisfactory function and bony union) being reported in from 60 to 100 per cent of cases.

Fig 3-2

Fig 3-3

Fig 3-2.—Base of the neck and intertrochanteric fractures. Outward rotation, upward tilting and eversion are the characteristic deformities. It will be noted that there is but little rotatory displacement of the head. It is practically all abduction. The proximal and distal fragments maintain some connection through the fibers of the capsule in *A*, the base of the neck and through the muscle attachments in *B*, the intertrochanteric. The lesser trochanter may be split off as a separate fragment and is then pulled upward and medially by the psoas. The greater trochanter may in part be a separate fragment. Such displacements of the trochanters as exist are of little or no significance. They are adequately cared for by flexion of the hip during treatment.

Fig 3-3.—Result of traction with abduction and internal rotation in intertrochanteric and base of neck fractures. The intertrochanteric fractures are adequately reduced by traction in slight or moderate abduction, probably because of the attachments which remain between the two fragments noted in figure 3-2. Pressure of the trochanter against the acetabular rim for rigid fixation purposes is not needed and therefore wide abduction is again unnecessary, as absorption at the fracture site is not ordinarily seen.

in some institutions. Under adequate care satisfactory function with bony union occurs in between 60 and 70 per cent of surviving patients. Under inadequate care close to 100 per cent failure of union has been reported in a large municipal hospital in one of our larger cities in a series of over 80 cases.

The mortality rate of primary operative treatment when open reduction is practiced in adequate hands is definitely lower than when closed reduction is practiced by the same surgeons or groups, running between

The average in a large series in good hands is probably about 75 per cent.

At present it can be said that operative fixation following closed reduction which will allow of early active mobilization of the patient and his extremity greatly reduces the mortality figures and through the prolonged immobilization of the fracture site it definitely increases the percentage of satisfactory results.

Regardless of the method of treatment used (whether closed reduction followed by plaster closed reduction followed by

ternal fixation through a lateral approach, or open reduction with internal fixation), in about 15 per cent of the patients showing bony union, degenerative changes in the head develop subsequently. Since these changes frequently do not make themselves clearly evident by x-ray for from one to three years after the fracture and since they frequently are accompanied by progressive pain and stiffness in the hip, the prognosis

This opinion is held because, while Christopher's series showed no cases in which non-union or subsequent deformity occurred and while others, with small series, have had the same experience, the author has seen 4 cases so treated in which absorption at the fracture line with resultant deformity and non-union has resulted. When the procedure of internal fixation through the lateral approach for any reason constitutes a real risk

Fig 374—"Well leg traction" (See figure 367 for principle involved) 1, Carl Jones splint. The central tube has a fixed lateral arm attached to or incorporated in the plaster on the leg on the sound side by means of a plate pivoted (adjustably) at C and D to allow the proper angle of the plate with the side. The arm on the injured side is moved on a worm rotated by handle E. P indicates heavy felt padding of the circular plaster which is very necessary. The plasters end below the knee. 2, Roger Anderson splint. A pin is put through the tibia on the injured side and incorporated in a circular plaster ending below the knee. The yokes A are then incorporated in the plaster, the circular on the sound side reaching to the region of the upper third of the thigh. The yoke on the injured side is perforated (small inset) to catch the pin. By reason of the pivots at B and C, progression of the traction screw D through its socket E (fixed to the arm on the sound side) in the direction of the arrow exerts downward traction on the yoke on the injured side. A spring keeps tension on the traction screw.

in hip fractures and the reports on results should take this fact into consideration.

When the fracture has resulted from a blow against the trochanter, with a resultant coxa valga position in impaction, the prognosis is in general excellent for bony union. Reported excellent results in such cases by the use of a short (knee length) abduction spica, elevation of the opposite heel and ambulatory weight bearing from the beginning (Christopher) without other fixation are increasing in number, but in the author's opinion, pinning should be done if possible

to the patient, on the other hand, the ambulatory method without internal fixation may be a justifiable procedure.

BASE OF THE NECK AND INTERTROCHANTERIC FRACTURE

In contrast to the intracapsular type of fracture, bony healing in fractures of the base of the neck is the rule, while it is almost without exception in intertrochanteric fractures (Fig. 360, 3 and 4). The mortality rate on the other hand, is as great as in the

Fig 3-5—Patient in thigh and leg skin traction in Thomas splint and Pearson leg piece. Compare with figures 3-6, 3-7 and 3-8 for diagrams of details.

Fig 3-6—Details of easily constructed metal frame designed for rapid assembly. Oak strips 2 1/2 inches by 3/4 inch and of desired lengths placed in one piece as per diagram fastening by single clamp (1). All screw construction in head and foot units. Desired lengthwise and crosswise pieces are fastened by a clamp working by a single throw of lever J and adjustable to all thicknesses up to 4 inches (Colt eccentric clamp no. 1—at any large hardware store). Piece resting on head or foot rail is curved to fit it.

intracapsular type. This is in accordance with the age group of the patients—about the same as that of the intracapsular type. The convalescent period is distinctly shorter.

in that from six to eight weeks usually sees bony union sufficient to allow of brace support, and such support rarely needs to be worn for more than three or four months. There is a tendency for the healing callus to remain soft enough to undergo gradual compression if weight bearing is allowed as soon as bony healing is apparent, with resulting *cova vara* deformity. The signs and symptoms are identical with those of the intracapsular type.

the abduction needed is much more moderate, since fixation of the trochanter against the acetabular rim is not necessary. The criterion is traction and abduction sufficient to give normal length and nursing ease, plus the inversion. The period of plaster treatment has been indicated, and the criteria for removal of plaster are the same as in the intracapsular fractures, plus the appearance of profuse visible callus in the intertrochanteric type. The splitting off of the trochanters in

Fig 377—Details of suspension for skin or skeletal traction. Thomas half-ring splint and Pearson leg piece. Upper left: Flannel supporting slings for splint and leg piece—doubled.

Upper right: Method of fastening with safety pins—easily adjustable, no interference with x ray.

Lower left: Suspension with straight knee. Suspending weight split into two increments for ease of adjustment—sliding weight A toward distal pulley raises distal end of splint, sliding it proximally from the pulley lowers the distal end of splint. Same holds true of increment B as regards ring portion of splint. Half ring splint with ring on top makes for ease of nursing and skin care. Whole ring can be used but is obviously less satisfactory. Foot piece E to keep foot from dropping into plantar flexion (weight F).

Lower right: Suspension with flexed knee. Hinged Pearson leg piece A attached to Thomas splint at level of axis of knee motion X and Y. Suspending weights E. Half ring on top. Rigid fastening between splint and leg piece (at D) when no active motion at knee is desired with skeletal traction or when it is not possible (as in skin traction). When motion is desired in skeletal traction rope from end of Pearson leg piece passes through two overhead pulleys to weight Z within reach of patient's hand and leg piece is left free to move at its hinge, patient's efforts at motion being aided if necessary, by manual manipulation of weight Z.

Treatment.—The treatment differs in that the reduction is accomplished by traction in mild or moderate abduction with inversion, is always easy to accomplish and is easy to maintain.

The methods available are:

1. **MANUAL REDUCTION BY TRACTION, MODERATE ABDUCTION AND INVERSION.** The outward pull during reduction is not needed in these cases. The broad surfaces of these fractures cannot be readily impacted nor do they need impaction. The reduction is followed by the single or double spica described under intracapsular fracture, excepting that

some cases is a matter of academic interest, but has little or no significance as regards treatment.

2. **THE "WELL LEG TRACTION,"** utilizing the principles shown in figure 367 and employing the apparatus shown in figure 374, is quite effective in these cases. It has the advantage of allowing the patient to be up in a wheel chair early. When this method is used, the inversion must be secured before the apparatus is applied. There is no need for the care of the traction apparatus, as described later, and the care of the patient's skin is of course easier. It is to be remem-

bered that there must be very heavy padding preferably thick felt beneath the plaster boots to avoid possible pressure on the peroneal nerve

3 TRACTION SUSPENSION IN MODERATE ADDUCTION AND INVERSION. This is effective in these cases it is not in the intra-capsular type. Skin traction as illustrated in figures 369, 375, 376 and 377 may be used if but little displacement exists. Skeletal traction using the Kirschner wire is preferable if much displacement is present. The wire is

present in a hernia operation. If under the conditions present infection is an appreciable risk it is the writer's opinion that there exists no moral justification for the use of skeletal traction except absolute necessity here or elsewhere. The amount of weight needed in traction is from 5 to 20 pounds or more depending on the degree of displacement and the size of the patient. The wire traction is obviously more effective in gaining and holding a position than is skin traction.

Fig 378.—Details of adhesive skin traction. A Adhesive strips molded to shape of leg and kept closely applied to skin by use of woven elastic bandage. Spreader of wood just wide enough to make adhesive strips clear the malleoli (a) and as close to sole as possible to prevent torsion of straps. Traction rope held by large knot on inner face of spreader. B and C details of spreader. Adhesive fastened by thumb tacks to spreader. B is anteroposterior view and C is bottom or outside surface of the spreader. D rope from spreader passes over pulley on frame or at foot of bed. E foot piece of adhesive (see Fig 377). Dotted lines represent woven elastic bandage to keep adhesive closely applied. F and G details of traction strap. Mole skin adhesive. Lateral tacks to aid molding to shape of leg. Adhesive side of strap facing reader. Dotted line in G represents small strip of adhesive to reinforce the junction between folded and unfolded portions of the strap where there is tendency for plaster to rip under heavy traction.

best placed through the femur as indicated in figure 380 but may be placed through the tibial tubercle. The advantage lies with the former method since it permits the employment of active mobilization of the knee from the beginning this cannot be done if the pin passes through the tibial tubercle. The only logical reason for using the tibial tubercle is that if infection occurs about the pin the knee joint is not threatened. If the technic described in figure 380 is employed there should be less risk of infection than is

4 RUSSELL TRACTION. This is illustrated in figure 379. It is simple to apply, more effective than ordinary skin traction but less accurately controlled. It is less effective than pin traction. It allows of great freedom of movement by the patient and is therefore of value in nursing care. In these fractures where union practically always occurs regardless of treatment it can well be used. The maintenance of adequate inversion in this as in ordinary skin traction suspension may present difficulties. The peroneal

nerve must be closely watched (foot drop and anesthesia or paresthesia over the dorsum of the foot) and the popliteal space watched for pressure.

The internal fixation of these fractures has been developed in recent years by the introduction of the Thornton plate attached to a Smith Petersen nail and by the development of the Moore blade. These can be applied through a lateral incision after closed reduction or open reduction. The Thornton plate attaches by a setscrew to a Smith-Petersen nail and is fastened to the lateral aspect of the shaft of the femur below by

The technique of application can be found by consulting the references cited at the end of this section.

Prognosis—Bony union occurs regardless of treatment, in practically 100 per cent of intertrochanteric fractures and in well over 90 per cent of fractures of the base of the neck. The mortality because of the age group runs as high as 20 per cent. It is highest in plaster immobilization and is increasingly lower as activity of the patient is allowed and enforced. The anatomical result varies with the accuracy of the primary reduction, the maintenance of that reduc-

Fig. 379.—Russell traction. The thigh and leg are supported on pillows. *A* is a sling underneath the knee and upper calf. From this a rope passes through an overhead pulley *B*. Skin traction is applied to the leg and incorporated in the spreader is a pulley *E*. Attached to the foot of the bed is a board holding a double pulley *CF*, or two pulleys close together. The traction cord from *B* passes through one side of the double pulley *G* then through the pulley on the spreader *E* and back through the other side of the double pulley *F* to the traction weight. The pull is a multiple of the weight owing to the double-pulley arrangement. The resultant of the two pulls as indicated by the large dotted arrow. Lowering the level of the pulley *CF* or placing the pulley *B* nearer the foot of the bed will alter the pull toward the horizontal. Raising the level of pulley *CF* or shifting pulley *B* toward the head of the bed will alter the pull toward the vertical. *G* is an overhead trapeze for use by the patient in shifting his position, to helping him to sit more or less upright and in raising himself to use a bed pan during bed changing etc.

three or more screws. The Moore blade is a flat metal blade with a horizontal arm and a vertical arm having the same angle to each other as the neck and the shaft of the femur. The horizontal blade has a cutting edged tip and is driven into the neck as one would drive a Smith-Petersen nail and the vertical blade is screwed to the lateral aspect of the femoral shaft. The use of one or the other of these appliances is displacing the more conservative measures described above with resultant improvement in maintenance of good anatomical position and marked lowering of the mortality rate.

tion and the protection of the primary healing against the combined elements of muscle force and weight bearing tending to produce coxa vara until the soft callus is adequately organized. (See Fig. 361, 3 and 5.)

SUBTROCHANTERIC FRACTURE

This fracture occurring at the upper end of the shaft and at the base of the great trochanter is characterized by marked abduction, flexion and external rotation of the upper fragment owing to the action of the practically intact musculature attaching to the trochanters and the intertrochanteric

line The net result is a very marked angular deformity just below the trochanter usually with marked shortening The often visible and always palpable deformity by its location distinguishes it from the neck and intertrochanteric fractures It is much more apt to occur in persons between thirty and fifty years old than in those in the earlier or later decades and is usually the result of rather severe and often direct trauma In keeping

pearance of callus alone is used as a criterion for release from immobilization

This fracture in common with all fractures of the femur demands for the best emergency treatment the use of the Thomas type of splint with fixed traction Such shock or wounds as the patient shows may then be treated with minimum damage to the fracture and maximum protection to the patient

Fig. 380.—Technic of pin insertion. Shave skin and clean with soap and water and alcohol. Iodine on the field. Drape adequately with sterile towels. Wear sterile gloves. A Skin bleb of novocain. Note site picked for pin—just above the flare of the femoral condyles. It avoids the joint cavity and also the nutrient vessels. B quarter inch skin nick with scalpel. C assistant pulls upward on soft parts on each side while novocain is injected through skin nick down to and into periosteum. The upward pull is maintained until the pin is fully inserted. D pin driven by hand or motor drill until it pulses skin ahead of it on opposite side. Novocain bleb is then raised and second quarter inch nick made allowing pin to come through. E pin is all the way through and upward pull on soft parts is released. Tissues now tend to pull away from pin's inferior surface, minimizing tendency to soft part pressure when traction is made. F dressing. Then circular piece of sterile absorbent cotton fastened to skin and to pin by collodion or rubber cement. Region of pin always visible for inspection. G yoke applied. Tension on pin made by turobuckle piece of snugly fitting sponge rubber (sterilized) between yoke and skin. Keeps dressing snug and minimizes possibilities that pin may slip from side to side.

with this the fracture is most often relatively transverse. The spiral and long oblique fractures from torsional strain are usually located farther down the shaft of the bone.

A second characteristic of the lesion is that while it almost invariably heals with but difficulty if reduced the healing callus remains soft for a considerable length of time and abduction angulation of the upper fragment is apt to occur if the roentgen ap-

The deformity with the extreme difficulty of controlling the short upper fragment makes it essential to carry out the reduction and immobilization with flexion at the hip and knee with outward rotation of the thigh and in sufficient abduction to align the fragments. The lower fragment constantly tends to drop behind the upper even when length and a normal axis have been secured and a forward lifting force has

ing The Stader or the Havnes apparatus may be similarly used The technic involved in use of the Stader Roger Anderson or Hoynes apparatus can be found in the references at the end of this section

Because of the frequent difficulty in securing and maintaining adequate position by any or all of these closed methods by reason of lack of control over the short upper fragment this site of fracture offers a primary operative choice when conditions warrant The discussion of this problem with the methods of fixation will be developed under the treatment of fractures of the shaft

Prognosis—These fractures reduced and given time enough rarely show non union but they characteristically show slow union The period of disability runs from five months up to nine months The mortality rate is dependent on the severity of the primary violence and coincident injuries and because of the prolonged immobilization time on the same complications to a lesser degree as are seen in fractures of the neck of the femur The lesser frequency of these complications is probably in relation to the less advanced age of the average patient

FRACTURE OF THE LESSER TROCHANTER

Isolated avulsion fracture of the lesser trochanter occurs by muscular violence It is rare The writer has seen three cases two of them epiphyseal separations in older children and one in a young adult after fusion of the epiphysis

It is apparently of little clinical importance The diagnosis is made by means of roentgenograms after violent strain (a take-off for a broad jump in one instance) resulting in pain and swelling with local tenderness in the groin and restricted and painful hip extension The fragment is displaced upward and medially by the pull of the psoas muscle

The simplest treatment is bed rest in the sitting position with knees and hips as acutely flexed as possible and early physical therapy to the muscles in the inner upper thigh region After from ten days to three weeks depending on the amount of primary separation gradual extension is practiced aided by physical therapy and after four weeks ambulation with crutches and active exercise of the hip are started

From six to eight weeks should see complete recovery

FRACTURES OF THE FEMORAL SHAFT

Fractures of the shaft constitute the second and great group of disabling fractures of the femur the intracapsular femoral neck being the first Under modern methods of treatment this seems unjustified if therapy is wisely chosen and adequately carried out from the beginning Only fractures of the shaft in adults will be discussed here In children the problem presented is entirely different and will be discussed later under the heading of fractures of the femur in children

In common with fractures of the shafts of other long bones the fracturing force may be either direct or indirect violence This is of more than academic importance in that direct violence is more apt to result in a transverse or short oblique fracture whereas indirect violence is apt to result in a long oblique or spiral fracture a matter which has some bearing on the method of treatment In addition in the direct violence type if compounded the fracture is usually compounded from without with considerable devitalization of the tissues in the region of compounding whereas the fracture due to indirect violence is compounded usually by penetration of a sharp fragment from within with much less bruising and contusion to adjacent soft parts

The age incidence is that of the exceedingly active period of life—active childhood and adult life before forty the majority in adults between the ages of twenty and thirty This is in a way fortunate because the patient is usually a young active individual and one in whom joint stiffening and muscle atrophy are not such threats as they are in older persons and the mortality threat of bed rest is not in evidence

It is in these cases particularly that the use of the Thomas type of splint with fixed traction as an emergency measure is of the utmost value Every hospital ambulance every hospital emergency ward and every doctor's office and automobile should be equipped with a Thomas type of leg splint and also a hinged ring arm splint (Murphy Jones) and its immediate use in actual or suspected fracture of the femur instituted

until definitive treatment is decided on. Although emergency traction is indicated in all fractures of long bones, it is so important in femur fractures that it is described here (Fig. 382). It prevents such situations as are commented on in the description of figure 383 and in general makes the ultimate reduction easier, the soft part pathology less, minimizes shock, minimizes the dangers of delay in reduction and keeps the patient remarkably comfortable. Its general adoption would constitute the biggest advance in

due to gravity distribution of the weight of the limb. It is therefore not only unnecessary to practice the inversion followed in fractures of the upper end of the femur but actually perverse. The x-ray film taken preliminary to treatment is of prime importance in that the nature of the fracture, line, the presence or absence of comminution and the exact relation and position of the fragments are extremely important in the choosing of the method to be used and the procedure for reduction.

Fig. 382.—Emergency traction. Steady firm traction is manually maintained while the ring of the splint is slipped over the foot and up the thigh to rest against the tuberosity of the isel um. A hitch of a linen bandage is thrown about the ankle over felt or cotton padding and tied taut to the end of the splint. A toe gauge depressor or rod of some sort is placed between the two pieces of bandage and twisted for the desired traction (so-called Spanish windlass). The leg is then fastened into the splint by bandage—continuous or a single tied loop above the ankle, one below the knee, one above the knee and one below the hip.

treatment of fracture of the femoral shaft made in a decade.

Diagnosis.—The diagnosis is made of course on the basis of the general signs of fracture—soft part pathology, deformity, embarking, shortening, angulation and rotation, false point of motion and in the absence of deformity, on localized pain and tenderness and functional loss. The rotatory deformity is of importance as regards therapy, since it is usually outward in both fragments in the upper due to muscle action and in the lower

Treatment.—The emergency immobilization, treatment of shock and handling of compounding or other soft part injuries are the same as in other fractures. The degree of shock is often a matter of importance since the fracture is frequently the result of severe violence as might be expected from the normal thickness and strength of the bone.

There is no best treatment for fracture of the femoral shaft. There is detailed below a list of the various tried and proved

methods available with the conditions under which each is best used. The methods are listed in the order of their theoretical efficiency based on abstract principles. It is readily seen that under any given set of circumstances a method listed low in the order of theoretical efficiency may be by far

Fig. 383.—Fracture of femoral shaft. Spiral fracture. Note outward rotation of lower fragment and outline of Thomas splint as used for emergency traction. The ring with small amount of soft parts intervening rests against the ischial tuberosity. The lower fragment was firmly embedded in the vastus externus and the upper half pierced the crureus and entered the rectus. The patient was seen and a Thomas splint applied several hours after injury and after two manual attempts at closed reduction there was overriding. Despite the emergency traction had the Thomas splint been applied immediately and the part kept under traction until adequate treatment was available the reduction might have been accomplished without the necessity for operation.

the best one to use. One of the reasons for the deplorable number of disabling femoral shaft fractures is the tendency to use a *method*. The remark, "I use such and such a method for fracture of the femoral shaft" indicates merely complete lack of comprehension of the problem and condemns a

certain number of patients to failure from the outset.

1. Open reduction with rigid internal fixation followed by balanced suspension and active motion in such suspension starting from five to seven days after operation.

This method of attack is on paper ideal. It secures anatomical reduction with a very small amount of real damage to the tissues; rigid fixation of the fragments without immobilization of joints; almost immediate resumption of at least partial function and complete accessibility to the soft parts of all forms of early physical therapy.

In practice to make this attractive picture a true one, one must have—

1. A patient who is an excellent operative risk.

2. A surgeon who has had adequate special training and experience in operative work on recent fractures.

3. Assistants similarly trained surgeons and nurses.

4. An operating room organization designed to facilitate the rigid detailed technique which is necessary without loss of time and with minimum trauma to the patient.

5. Equipment (instruments, etc.) designed to facilitate the ease of operative reduction and minimum of trauma to the tissues and security of internal fixation.

6. A fracture of such type as regards comminution, line of fracture, etc., that rigid fixation at operation is insured.

7. An organization adequate for insuring that postoperatively the patient's balanced suspension will be properly set up and properly maintained and that active mobilization will be adequately and safely carried out.

This is a most demanding set of circumstances. The answer is, of course, that there are very few places where the procedure as outlined can be pursued as a method of choice with safety. It is important to realize that the result and the safety of the procedure depend less on factor 2 than on the others listed. A surgeon who fulfills the requirements listed under 2 is often deluded into believing that he is the most essential factor. One cannot emphasize too much the fact that this is a delusion. Unless all of the factors listed are present, the choice of this method is neither safe nor sane. There is here neither time nor space to go into the

question of operative treatment of fractures in detail. But even the little which has been indicated should give the idea that this method is not one that is suitable for use by the average surgeon.

Figures 383 and 384 show a typical spiral of the femoral shaft treated by the above method. This patient was never in plaster, was walking on a caliper splint at six weeks, had a practically full range of motion in the hip, knee and ankle at that time and was back at clerical work in three months and walking without any support and with full

II Traction suspension with a Thomas splint and the Pearson leg piece and skeletal traction and active mobilization.

This method should provide fairly rapid reduction with a minimum of trauma, considerable functional activity of the part during healing, rapid abolition of soft part pathology through elevation, active muscle function within pain limits and early physical therapy.

The indications for its use are—

1. A patient who can be kept in bed for six or eight weeks or longer. This involves

Fig. 384.—Plated fracture of femur. Fracture shown in figure 383 after plating. The anatomical replacement of the fragments is obvious and the rigidity of fixation is such that active mobilization in balanced suspension has been started five days postoperatively. Since the splint is merely being used here as a suspension apparatus there is no necessity for having the ring under the tuberosity of the ischium for counter traction as is the case in figure 383. This form of fixation utilizes a long plate with six screws passing through both cortices of the bone. It is, however, a fixation in only one plane and is not as safe or as logical as the fixation shown in figure 385.

function at four months. He was treated under conditions fulfilling all the requirements listed. For every such case there can be shown at least ten others in which the surgeon considered only his own excellent operative ability. These patients have taken a longer time to recover and have a poorer functional result than if they had been treated by a closed method.

Operative reduction followed by plaster immobilization as a primary procedure of choice gives a good x-ray picture but is more apt to prolong the convalescence than to aid it.

physical, economic and mental/emotional factors.

2. An organization capable of properly applying and maintaining the apparatus and of insuring the practice of active motion by the patient.

3. A patient who can be reasoned, cajoled or bulldozed into practicing active motion as directed.

4. The use of surgical precautions in the insertion of the skeletal traction.

5. The line of fracture which particularly calls for this type of treatment is the oblique and spiral and the comminuted in which

maintenance of reduction is difficult by plaster

The details of the traction suspension are discussed under intertrochanteric fractures and are illustrated in figures 369 375 376 377 and 380 Lateral and anteroposterior displacements can be corrected by appropriate sling and pulley weight pull

An essential point in all traction-suspension is to accomplish reduction in hours—not in days or weeks After reduction is accomplished at least weekly roentgenographic checks should be made for position and healing

tained The advantages of active motion and early physical therapy as indicated under II are lost

The reduction as indicated under II may be followed by a plaster spica as soon as reduction is accomplished The Anderson well leg traction or the Hoke well leg traction may be used in fractures of the femoral shaft The author does not recommend them The other methods described are more satisfactory

The Stader Haynes or Roemer Anderson apparatus may be used They are not as satisfactory in the femur as they are in other

Fig 343.—This type of fixation is preferable to that shown in figure 341 The length of the plate is between four and five times the diameter of the bone the screws which fix it pass through both cortices and in addition two screws are inserted obliquely from one fragment through the other in a plane relatively at right angles to the plane of the screws fixing the plate This gives fixation in two planes and relieves the plate and the screws fixing it from torsional strain and shearing strain This greatly reduces the possibility that the plate or screws will become loose under the strain of functional activity If there is a loose intermediate fragment it should be fastened to one of the main fragments by means of screws before the plating and the screw cross fixation are done This is the method routinely used on the Fracture Service of the Presbyterian Hospital in New York with very satisfactory results

The line of traction and suspension is indicated by the position of the proximal fragment

The length of time that traction is maintained is gauged by the x-ray film and clinical evidence of union

The removal of traction is followed by the use of a caliper brace for a varying period or the progression from crutches to cane depending on the strength and amount of callus and the weight of the patient

III Reduction by skeletal traction followed by or accompanied by immobilization

The value of reduction within a question of hours with a minimum of violence is re-

quired For the technique of their use the references listed at the end of this section should be consulted

Skin traction with a Thomas splint and the Pearson leg piece is suitable only for those patients with little or no displacement and for whom it is desired merely to maintain position during healing In view of the fact that it does not safely allow active mobilization and in view of the relatively complicated arrangement as compared with the Russell traction it should be displaced in these days in favor of the latter

IV Russell traction (Fig 379) This secures adequate traction allows early phys-

cal therapy, allows great freedom of the patient's movements in bed simplifies the nursing care is simple to apply and requires practically no special apparatus. It is less secure than when a Thomas splint and the Pearson leg piece limit lateral and antero-posterior movements of the fragments. It does not allow safely of any degree of active knee joint motion.

Indications for its use are

- 1 Lack of equipment
- 2 Lack of organization for application and maintenance of it
- 3 Danger in use of skeletal traction (skin infection in patient surgical technique difficulties in the operating room or personnel necessity for treatment in the home)

V Manipulative reduction followed by plaster immobilization

This can be carried out anywhere. It requires no apparatus and no particular organization. After care is limited to checking on the position at weekly or bi-weekly intervals and nursing for skin care and positional change. Little or no hospitalization is required. The reduction can be done under local anesthesia.

The method is in itself disabling because of the relative violence of the manipulations required (often as great as or greater than that of the original fracture) and because of absolute and often prolonged immobilization of the part with inability to carry out an early attack on the soft part pathology by physical therapy. In cases of oblique spiral and comminuted fractures it is less apt to secure good position and less apt to maintain it once it is secured. It is more apt to result in skin and pulmonary complications.

The chief indication for its use is absolute necessity because of inability to use any of the preceding methods.

It is a matter of importance to realize that the choice of the best treatment available under the circumstances should be made when the patient is seen and should be immediately instituted. The rationale of trying the simplest and easiest known method first (unless it is the only one possible) and progressing, after each failure, to the next more efficient though more difficult method shows not only poor surgical judgment but is evidence of lack of common sense and is

responsible in large measure for poor results. The problem is not that of what is the easiest way in which the condition can be treated but rather what is the most efficient way in which the problem can be handled under the circumstances.

Following union the usual routine of exercise aided by physical therapy and/or occupational therapy is instituted. Weight bearing with brace support or crutches progressing to cane and then full weight bearing is followed in accordance with clinical and x-ray evidence of consolidation of the union for all these methods.

VI Operative reduction as a matter of necessity

It is important to recognize the indications for this as early as possible. Operative treatment following non union is far less effective than early operative intervention.

The indications are

- 1 Interposition of tissue as indicated by failure to secure bony contact (crepitus) during manipulation or the application of traction
- 2 Vascular or nerve lesions at the fracture site warranting emergency intervention
- 3 Extensive comminution particularly from without
- 4 Inability to obtain or to maintain satisfactory position by non-operative means with reasonable efficiency. The procedure of operation and the postoperative handling are based on the indications that have already been enumerated.

Prognosis.—The shaft of the femur that is adequately cared for is usually healed in from six to ten weeks. It may require from twelve to fourteen weeks. Weight bearing with brace is usually possible at that time (walking caliper Fig 368).

In general all other factors being equal the convalescence time to full function and walking ability increases with the method of treatment used in the order as listed and varies with the patient's occupation. This gives a keenness of from four months to a year or longer.

The mortality in the average case should depend almost entirely on the question of shock and other coincident injury except in the aged in whom the factors described under fracture of the neck of the femur become a matter of importance.

SUPRACONDYLAR FRACTURES

Supracondylar fractures, while not exceedingly common are rather difficult to handle because of the characteristic deformity (Fig 386). The age incidence is fortunately that of the young and middle-aged adult group. The healing time is somewhat slow normally, and this is a factor of importance in the election of a method of treatment.

The diagnosis rests on the presence of the local signs including a characteristic bowing of the thigh above the patella, the bow open forward. There is shortening in extension with the degree of over riding. Lateral or medial angulation also may exist of

listed under fractures of the femoral shaft with the same indications and subject to the same reservations.

When skeletal traction is used traction in the direction of the femoral shaft must be aided by a lifting sling under the lower fragment and/or the application of the Pearson leg piece just at or just below the fracture (Fig 386).

When plaster immobilization is used the knee and hip must be in sufficient flexion to maintain correction. This requires the type of semi sitting splint described under subtrochanteric fracture.

Well leg traction is not adapted to the treatment of this fracture, and ordinary skin

Fig 386—Supracondylar fracture. A Characteristic deformity maintained by gastrocnemius. B Effect of flexion of knee in relaxing gastrocnemius. C Further effect of combining some knee flexion with a Thomas splint and Pearson leg piece having the leg piece angled at the site of fracture instead of at the axis of knee joint motion (compare with Fig 377). In the illustration a supporting framework in the nature of an inclined plane similar to the Brum, B'ler etc., fracture frames mentioned in the text is shown with the change in incline occurring at the fracture site instead of at the knee joint. It is obvious that with a little more traction the weight of the part will correct the anteroposterior displacement and the flexion of the knee and the angulation of the splint will correct the angular deformity.

course. The lower fragment is usually rolled outward.

It is necessary in reduction regardless of the method used to exert three forces—traction in the line of the femoral shaft, rotation of the lower fragment in the anteroposterior plane in which the lower end goes backward and the upper end forward and a lifting force on the lower fragment as a whole (compare with subtrochanteric fracture) to overcome a gravity effect resulting in posterior displacement. The second of these forces is accomplished by the necessary degree of knee flexion plus a fulcrum (hand suspension or sling) at the level of the fracture (Fig 386).

The choice of treatment runs about as

traction is of little value. The Russell traction is probably not at its best in this type of fracture. The very low supracondylar fracture is not suitable for operative treatment.

Prognosis.—The healing time in this lesion in adults is usually from eight to twelve weeks but it may run to fourteen or sixteen. There is a corresponding prolongation of the convalescence as compared with that in cases of fractures of the main portion of the femoral shaft. The remarks made on the mortality in fractures of the femoral shaft apply equally here.

CONDYLAR FRACTURES

Condylar fractures are rare and of two types. A single condyle or both condyles are

split off usually as a result of severe violence of a more or less direct type with accompanying hemarthrosis of the knee joint.

Pin traction through the tibial condyle is indicated as the primary procedure of choice in the position calculated to secure reduction dependent on deformity.

If the displacement is exceedingly great or if in from twenty four to forty eight hours it is obvious that pin traction is not effective then operative reduction and fixation are indicated. The results of operative treatment may be excellent roentgenographically but the lacerations of the soft parts within the joint frequently lead to prolonged difficulty in regaining mobility. The same difficulty is encountered in other methods of treatment.

The second type almost invariably involving the external side is that in which the femoral condyle is impacted upward by forcible abduction of the leg on the thigh as when the patient is struck on the outer side of the leg by an automobile bumper or fender while the foot is fixed (Fig 387). This gives local symptoms over the outer aspect of the lower femur usually hemarthrosis and a varying degree of possible abduction of the leg on the thigh in full extension a possibility not present in the normal knee joint to any appreciable degree. The amount of abduction possible depends entirely on the degree of impaction of the condyle viz elevation of the external condylar surface. If this abduction is possible to more than 10 or 15 degrees the fragment either should be malleted down to its normal level or if this is impossible should be operatively replaced and fastened. When the abduction is not sufficient to warrant correction or following correction as indicated the best treatment is by suspension with mild (3 to 5 pounds) traction on the leg and active mobilization as indicated heretofore—preferably with a Thomas splint and the Pearson leg piece.

Union is inclined to be slow and the healing callus must be protected for some time against full weight bearing either by brace or crutch. The time required for union is usually six to eight weeks and it is usually from twelve to sixteen weeks before full weight bearing can be allowed.

If it has been unnecessary to correct the

displacement a brace or crutch can be used after two weeks and full weight bearing can be attained in six or eight weeks.

Aspiration of the hemarthrosis is indicated when the joint is not operatively opened and repeated if necessary.

Fig 387.—Contour of fracture of external condyle. The dotted outline represents the normal. The abnormal abduction which can be elicited is obvious.

The usual attention is paid to active motion and the pathology of the soft parts throughout the course.

FRACTURES OF THE FEMUR IN CHILDREN

The problem presented in children is different in many respects from that in adults. The fracture of the neck of the femur is represented in this group by separation of the upper femoral epiphysis. Supracondylar fracture occurs in older children but in younger ones it is represented by separation of the lower femoral epiphysis. Fractures of the shaft are common but do not have the disabling character of those in adults owing to compensatory powers present in childhood which make the problems of prolonged immobilization and of deformity matters of much less consideration.

Upper Femoral Epiphysis.—One must distinguish between three separate conditions in this region each of which may present a history of injury with pain and swelling about the hip joint and with shortening and abduction and eversion deformity. There are true traumatic separations of the upper femoral epiphysis, separation associated with the epiphysis of the Trichard syndrome (obesity and backwardness of primary and

secondary sex characteristics) in which very mild trauma is the rule and Legg Perthes' disease in which no real displacement exists.

The true traumatic separation requires relatively severe violence for its production. The other two may present such a history but usually present themselves after mild trauma and careful questioning of the child or its parents will elicit a history of previous trouble with the hip of a mild nature (slight limp, disinclination at times to engage in violent play with other children and complaints of intermittent mild pain).

The roentgenograms of the first and second conditions may be identical except that in the latter there is evidence of irregularity and abnormality in the epiphysis on the

diagnosis is almost certain and the roentgenogram gives definite evidence.

Treatment—Whether the case belongs in the first or the second group the reduction is best accomplished by the Whitman procedure and followed by the Whitman spica (see Fracture of the Femoral Neck). There is no need in these cases for outward traction on the thigh.

If the child is normal immobilization in the spica for from eight to twelve weeks is indicated followed by gradual resumption of weight bearing. If the child shows a Frohlich syndrome the immobilization period should be doubled and once weight bearing has started careful and frequent roentgenographic checks for recurrence

Fig 388

Fig 389

Fig 388—Separation of upper femoral epiphysis. It can be readily seen that abduction is essential to reduction of the displacement. Dotted line represents very mild degree of displacement evidenced by slight tilt of head and slight bending of upper end of the epiphyseal line.

Fig 389—Legg Perthes' disease. It will be seen that the head lies in its normal position, it is flattened and the ossification center is dense and is flattened and fragmented.

normal side (Fig 388). The child's physical characteristics of course establish the diagnosis. In fact in any child of the Frohlich type who complains of pain in the hip with or without trauma a slipped epiphysis should be suspected.

The picture in Legg Perthes' disease is quite different and differentiates the condition from the epiphyseal separations (Fig 389).

The diagnosis of slipped epiphysis is based on the history of trauma, the local signs of pain and tenderness with limitation of motion and spasm in the hip joint and if enough deformity exists corresponding degrees of shortening, eversion and adduction. If the patient is of the Frohlich type the

should be made. If there is a recurrence operative reduction and fixation (probably best by the Smith-Petersen nail) is indicated.

In the true traumatic cases the prognosis is excellent in the majority of cases. A small percentage probably around 5 per cent show disturbances of growth in the head with deformation and traumatic arthritis subsequently. This is worthy of note since not only must the child be followed with this in mind but in every case it is the part of wisdom to call the parents' attention to the fact that it may occur. There is no way of telling in which case it will occur since the amount of separation seems to be no criterion. If it does occur and the parents

have not been warned of the possibility they frequently consider that the treatment was responsible for the subsequent difficulties. In the Frohlich cases the prognosis is always dubious since coexisting disease of the epiphysis is present. It is probable however if the condition is recognized early if accurate reduction is accomplished and if prolonged immobilization is practiced that the outlook is not too poor. In view of the prolonged immobilization needed and the possibility of recurrence primary closed or open reduction plus the insertion of a Smith Petersen nail in adequate hands is coming to be looked on with increasing favor.

Separation of the Lower Femoral Epiphysis—This is characterized by one of two displacements that characteristic of the

displaced backward or downward and backward pressure if it is displaced forward (Fig 390). It is frequently difficult of accomplishment. Prolonged and steady traction (five minutes at least better ten) under anesthesia preceding the actual manipulation is probably the greatest aid to success.

The immobilization is with the hip and knee in flexion in the semi sitting position described under subtrochanteric and supracondylar fractures. It should be maintained for six or eight weeks.

If manual reduction is not possible in view of the fact that operative reduction is rather to be avoided Russell traction may be used for forty eight or seventy two hours and may be successful with the possibility

Fig 390—The deformities in lower femoral epiphyseal separation. A Anterior displacement of lower epiphysis. B posterior displacement (as in supracondylar fracture) of lower epiphysis. The direction of the reduction forces described in the text are illustrated by arrows and their effect is obvious.

supracondylar fracture or that in which the metaphysis goes forward instead of backward (Fig 390). In the writer's experience the former has been more common but in the available statistics the latter would seem to be more frequent.

At any rate the indication is for closed reduction if it can possibly be done. This is true of any epiphyseal displacement in the absence of epiphyseal disease since operation probably increases the chances of subsequent growth disturbances.

Manual reduction is preferable and consists in hyperextension of the lower fragment with the knee flexed traction in the direction of hyperextension using the flexed leg as a lever and direct downward and forward pressure on the lower fragment if it is

that gentle manipulation under anesthesia as the patient lies in traction may be needed in addition. If reduction is secured the traction is removed and the splint applied.

The prognosis is excellent except in those cases in which subsequent growth disturbance occurs. This is a most serious complication since it leads depending on the youth of the patient to anywhere from 1 or 2 to 5 or 6 inches of shortening as growth on the normal side progresses. Sometimes only half the epiphysis—inner or outer—shows any disturbance. In this event an increasing deformity develops in the knee leading to varying degrees of unilateral knock knee or bow leg. Femur lengthenings, destruction of the epiphysis on the sound side or of the sound portion on the injured side and vari-

ous osteotomies may be called for and the decision as to what to do and when to do it may be extremely difficult. It is therefore most important that the remarks made under discussion of the upper epiphysis as to warning parents at the outset of the possibilities and as to keeping the patient under observation after treatment be kept in mind.

Fractures of the Shaft—In fractures of the shaft of the femur in children one must seek restoration of the normal axis in both planes: correction of rotation, normal length and end to end apposition. But if there persists up to 1 inch of shortening or angula-

or to operative approach provided the deformities are no greater than those previously cited. Operative approach and skeletal traction in children require considerable justification. The former should be used only in the event of compounding or of interposition of tissue preventing closed reduction. The latter only if in the presence of comminution or extreme obliquity of the fracture line (particularly if compounding co-exists) it seems impossible to keep the residual temporary deformity within the limits previously prescribed for conservative measures or if for any reason the use of the more conservative measures to be detailed is interdicted. When skeletal traction is used, tongs should never be resorted to. Wire traction as described under fracture of the shaft in adults is indicated.

In the newborn fractures of the femoral shaft are best treated by the use of well

Fig 391—A Bryant traction. It will be noted that the buttocks swing just clear of the bed. The legs must be spread enough to allow easy nursing. The adhesive traction strap is covered by a woven elastic bandage. This is of great value in minimizing the chances that the adhesive will slip. This type of traction maintains position in the younger children remarkably well despite their twisting and turning. B LeMessurier traction. 1 Represents a Brafford frame fastened at an angle to the foot of the bed on which the patient lies. The inclination makes his body weight act as a countertraction force. There is a flap in the canvas at 4 for nursing purposes. The thigh and leg rest suspended in a Thomas splint. Adhesive traction straps, 3, covered by a woven elastic bandage to minimize slipping. 2 are fastened to the end of the Thomas splint, and the Thomas splint in turn is tied to the foot rail of the bed. Traction is furnished by the pull of the patient's body weight against the adhesive fixation to the fixed Thomas splint.

tion of 5 to 10 degrees or 10 to 15 degrees of rotation despite the best of efforts in children up to eleven or twelve years of age there is not the occasion for worry that such a situation would engender in the adult. In the course of subsequent growth such deformities will be almost invariably corrected and there will be no sequele. This does not mean however that one should not attempt to secure anatomical replacement. It merely means that if conservative methods fail to secure anatomical replacement there is no necessity—actually no excuse—for resorting to repeated re-reductions

provided light basswood correction splints. They may heal with considerable deformity but without exception they heal and correct the deformity by growth quite rapidly. The attempt to secure accurate reduction and immobilization is a gesture that does more harm than good. The parents should be given to understand the rationale of what may seem to be inadequate treatment otherwise any temporary deformity may cause considerable alarm.

In children up to five years of age the preferable form of treatment is Bryant suspension (Fig 391). This traction is in 210

trained until roentgenographic and clinical evidence of healing have been obtained. No further treatment is indicated. It almost invariably leaves some residual deformity temporarily but anatomical normality as the result of growth adjustments invariably occurs after one to three years. Plaster immobilization in children is unsatisfactory. The plaster soils and softens from excreta frequently and thoroughly requires frequent change and is apt to irritate the skin badly. The contraindication to Bryant traction is an inability to keep the child in a hospital or to provide adequate supervision of the traction straps at home.

For older children manual reduction followed by plaster spica immobilization or the use of traction suspension of the skin type, either that described under intertrochanteric fracture in the adult or the type used by LeMesurier, is indicated (Fig. 391). The latter is best reserved for long oblique and spiral fractures and for comminutions and compoundings which can be handled without the use of skeletal traction.

When plaster immobilization is used in oblique and spiral fractures, traction straps of adhesive are attached to the leg following reduction, the plaster spica is applied leaving the foot free, and the traction straps are brought up around the edge of the plaster and incorporated in it.

It is of note that position must be secured early in these cases, as union is appreciably more rapid than in adults. In children over twelve or thirteen years old the methods used are those used for adults but manual reduction and plaster and skin traction suspension are the most desirable methods.

Prognosis.—The immobilized joints practically never present any difficulty, and function usually returns under no other treatment than active exercise. Moderate deformity, as indicated, is almost invariably taken care of by growth. Union in small children is usually complete in three or four weeks. In the older group five or six weeks at the latest sees solid union and weight bearing at eight or ten weeks is a conservative estimate.

FRACTURES OF THE PATELLA AND OTHER SESAMOID

Sesamoid bones are the result of the detachment of ossification centers and are more or less regularly embedded in tendinous structures overlying certain joints. These appear to be more or less incidental functionally and do not interfere with the tendon action. As a matter of fact, they may be an asset to more accurate motion and may help to increase the padding in certain locations, such as in the plantar surface of the metatarsophalangeal joint of the first toe and the metacarpophalangeal joint of the thumb. There are other minor sesamoids that are doubtless developmental or evolutionary remains and are of no functional importance. The patella represents by far the largest sesamoid in the body and is of great

importance to the perfect function of the knee joint. Injuries of this bone are not uncommon and warrant careful treatment. All the other sesamoids are better protected, and injury comes to them usually secondary to more severe trauma to the surrounding parts. Excision of such injured minor sesamoids can be carried out without interfering with the ultimate function of the neighboring structures. Delayed or non-union causing prolonged disability may make it necessary to resort to this radical form of treatment.

Anatomy of the Patella.—This large sesamoid is rarely absent. It is spoken of as the "kneecap" and the "kneecpan," rarely as the "kneepad." In the adult it varies somewhat in size and shape but is roughly the shape of a broad, thick shield and is about 6 cm long, 5 cm. wide and 2.5 cm. thick. It is slightly convex. The under surface is covered with cartilage and articulates with the condyles of the femur when the knee is flexed. The edges are slightly thinner than the center. The edges and anterior surfaces are firmly attached within the tendinous portions of the quadriceps femoris anteriorly, the vastus internus internally and the vastus externus on the outer side. The tendinous extensions of these various structures unite around the patella, save on its articulating surface posteriorly, and continue on the inferior border to form the strong fascial structure called the "prepatellar tendon," which is attached to the tibial tubercle. Thus, there is a bony structure lying within the great extensor tendon of the knee joint which is of importance to the perfect functioning of this complicated joint. It can be eliminated when necessary because of disease or severe trauma, and the knee will be reasonably serviceable; but careful repair of this sesamoid should practically always be attempted and will usually result in a successful outcome.

Congenital anomalies of the patella are not unusual and are often mistaken for fractures. The most common anomaly is represented by a detached fragment of the upper outer quadrant. It was present in 3 per cent of a series of 63 cases of patellar injury reported by Adams and Leonard.¹ The condition is usually bilateral, and a roentgenogram of the opposite knee will help in the

no separation of fragments, the knee should be splinted and elevated until all the excess fluid in the joint has been absorbed (two weeks). Aspiration under careful aseptic conditions may be performed to advantage after the third or fourth day and repeated if necessary. The leg should then be encased

fragments. operative treatment should be instituted. Some surgeons prefer to operate as early as possible, but the majority prefer to wait until hemorrhage has subsided and the joint effusion has been partially absorbed and then operate. The average delay entailed is five days, during which time the joint is

in well padded plaster of paris from the ankle to the groin with the knee in extreme extension. Weight bearing with crutches may be allowed between the third and sixth week, then a cane may be used. The leg should be supported with the plaster of paris case until after the eighth week.

In cases in which there is separation of

splinted and the leg elevated. The capsule may be sutured with cotton silk or fine steel wire and nothing done to the bone itself. When this method is used delayed motion and long splinting may result in considerable loss of function and refracture may take place. Some surgeons prefer to drill the fragments and hold them in apposition with

wire, but the majority of surgeons prefer the use of fascia lata in the repair. The fragments may be drilled and held together with a strong piece of wire or a large plaque of fascia may be sutured to the quadriceps above and the prepatellar tendon below after the fragments have been approximated and the capsule has been sutured.³ The capsule itself may be sutured with fascia. A portion of the quadriceps tendon may be detached passed through drill holes and sutured on itself.⁴ Whatever method of repair is chosen the most important detail is the suturing of the rent in the lateral expansions of the capsule since the object is to restore continuity in the extensor tendon of the knee joint. The bone itself is helpful but is incidental. Brooke⁵ has advocated excising the patellar fragments and discarding them. We believe that this method is most useful in a badly comminuted compound fracture. The tendinous structures should be carefully repaired. The advantages of wire and fascia fixation are principally that they permit early motion and restoration of function. Disability is thereby greatly shortened.

FRACTURES OF THE TIBIA AND FIBULA (SHAFTS AND UPPER ENDS)

Anatomical Considerations.—The two tibial spines (medial and lateral) the tuberculum intercondylare mediale and the tuberculum intercondylare laterale should always be kept in mind while studying an injury about the knee joint since fracture of one or both may result from a severe twist or partial dislocation.

The tibial tubercle which affords the attachment of the ligamentum patellae arises from its own bony nucleus which in early life unites with the upper

epiphysis of the tibia. It is particularly exposed to trauma such as direct blows and to the strain resulting from violent contraction of the quadriceps extensor muscle.

The upper end of the tibia sometimes called the tibial plateau constituting the weight bearing surface with which the lower end of the femur articulates is frequently fractured. The external tibial condyle or the internal tibial condyle may be split off and displaced laterally or may be driven downward. Extensive comminuted fractures of the upper end of the tibia may also occur without injury to the bones otherwise.

The shaft of the tibia is subject to all the varieties of fracture. It is rare however to find a fracture of the shaft of the tibia without a fracture of the fibula and when this does occur it is usually the result of direct violence *vice versa* the shaft of the fibula is seldom fractured without an accompanying fracture of the tibia and when the fibular shaft alone is fractured it is the result of direct violence. The upper end of the fibula articulates with the tibia and fractures of this portion of the fibula alone are usually the result of direct violence.

Both bones of the leg are fractured with the greatest frequency the fractures occurring at any place in the shafts of the bones. The most common site of fracture of the shaft of the tibia is in the middle third and the fracture of the fibula is usually at a higher level. A fracture of the tibia with overriding of the fragments always means an injury to the fibula, an injury which should be located. The fractures are too rarely transverse the most common being the oblique fracture. Spiral fractures and comminuted fractures occur with great frequency.

Etiology.—The tibial spines are injured when as a result of trauma one of the femoral condyles strikes the tibial spines and knocks one or both from the attachment.

The tibial tubercle which is a prolongation of the proximal epiphysis downward on the anterior surface of the tibia is always exposed to direct trauma. The ligamentum patellae also inserts into the tibial tubercle and as a result of violent contractions of the quadriceps muscle the tubercle may be partially or completely loosened from the underlying shaft of the tibia.

The upper end of the tibia is frequently injured when a person is struck by an auto mobile bumper which is at about the level of the knee joint. A fracture of one of the condyles of the tibia may be produced by this trauma. Tackling in football and falling downstairs may produce a similar injury. A fall from a height as from a railway box car may produce a severe comminuted fracture of the upper end of the tibia.

The shaft of the tibia may be fractured as the result of turning quickly with the foot

fixed. Starting with this simple etiologic factor it is readily understood that there are innumerable forms of direct and indirect violence which may produce a fracture of the shaft of the tibia. The shaft of the fibula is usually fractured at the same time and at a higher level.

A fracture of the tibial shaft or of the fibular shaft without fracture of the other bone is always the result of direct violence such as the kick of a horse or similar direct force.

Pathology.—Fracture of the tibial spine is often an incomplete but when it is complete the spine becomes a foreign body in the knee joint.

The tibial tubercle fracture is usually incomplete and the separation and elevation of the tubercle result in an increased prominence of this region.

Fractures of the upper end of the tibia involving the knee joint always produce hemorrhage into the knee joint. Secondary adhesions may develop in and about the joint and thickening of the connective tissue elements surrounding the joint also results. The articular surface of the tibia is widened and the ligaments surrounding the joint are forced into abnormal positions. Disturbances of the attachments of the crucial ligaments may be produced. The semilunar cartilages may be injured either in the cartilaginous portions or in the ligamentous attachments. Fragments of bone may become detached and may become foreign bodies in the knee joint. The formation of excess callus extending into the knee joint is unusual and is thought to be prevented by the action of the synovial fluid.

Fractures of the shafts of the tibia and fibula produce the same pathologic changes as fractures of the other long bones. The minimal changes are negligible and the maximal changes may produce very great permanent disability. Blood escapes into the soft tissues surrounding the bone and follows the arterial sheath producing ecchymosis in the most dependent areas. The sharp ends of the bone may lacerate the surrounding periosteum, muscles, tendons, blood vessels, nerves, lymphatic vessels, fascia and even skin. If the skin is lacerated the fracture becomes compound and infection may occur.

The damage produced in the soft tissues by the sharp ends of the fractured bone and the escape of blood into the soft tissues both from the ends of the broken bone and from torn blood vessels cause interference with the return circulation of the extremity. The circulatory stasis produces swelling which is especially marked during the first few hours. The inflammatory reaction of the tissues to injury begins at once to stimulate the formation of permanent new tissue in the same manner as elsewhere. The fluid which has accumulated in and between the different soft part structures is accompanied by the various cellular elements which increase in number and produce permanent inflammatory changes and new tissue which is not removable. These early pathologic processes should be kept in mind particularly in fractures of the shafts of the tibia and fibula.

When the tissue fluid collects in excessive amounts in the leg where there is only limited room for expansion one frequently sees the formation of large blebs of fluid covered by superficial layers of skin.

Symptomatology.—Fracture of the tibial spines never occurs as an uncomplicated injury. The symptoms are pain and swelling in and about the knee joint. If the knee joint is aspirated blood stained fluid is obtained.

Fracture of the tibial tubercle occurs most often as an uncomplicated injury to the tibial tubercle with pain and swelling at this point. The symptoms are increased by flexion of the knee thus increasing the tension of the patellar tendon.

Fractures of the upper end of the tibia always produce swelling of the knee joint. Movements of the knee joint are painful and the knee is weak and unstable, the instability varying with the extent of the fracture.

When only the shaft of the fibula is fractured tenderness and swelling and later ecchymosis develop about the site of the fracture. Weight bearing may be possible. When only the tibial shaft is fractured there is tenderness and swelling about the site of fracture but if the fracture is complete weight bearing cannot be tolerated. When the shafts of both bones of the leg are fractured there is pain, tenderness and swelling at the site of fracture and abnormal mobility.

Diagnosis.—When a bone is fractured or when a fracture is suspected the diagnosis should be made by means of properly taken x-ray pictures. Anteroposterior and lateral views should be taken on films large enough so that the injured area may be completely studied but not so large as to cause distortion of the portions at each end of the film. If a complete diagnosis of the fractured bone is not thus obtained further roentgenograms should be taken. It is more important for the student to familiarize himself with the normal physical findings and with the conditions due to trauma which are not fractures and thus be able to rule out a fracture than it is to know and use the twentieth century methods of diagnosing fractures. A review of the foregoing paragraphs regarding the pathology should suffice to prevent anyone from an effort to obtain the signs of abnormal mobility or of crepitus. The obtaining of more evidence of abnormal mobility than that indicated by the slightest

diagnostic movement or the moving of the broken fragments sufficiently to cause crepitus is no longer justifiable. Pain and tenderness may be searched for and with a proper history may indicate the necessity of an x ray study. Echinosis following an injury which may have caused a fracture places the burden of proof on the person who says there is no fracture therefore an x ray examination is indicated.

A proper and complete diagnosis is highly economical in industry because if a fracture exists the earliest possible appropriate treatment will produce earlier and more complete recovery and therefore an economic saving to both patient and employer. On the other hand if it is possible that a fracture has been sustained but the x ray plate shows that none is present then the patient may return to work with a minimal loss of time again to the advantage of all concerned. Similarly in the aged the young and the unemployed when a fracture cannot be ruled out a roentgenogram should be obtained because of the resulting economic advantage to the patient.

Up to the time when the fracture is sufficiently healed to prevent changes in the relation of the fragments from occurring it is necessary to repeat the x ray studies and re-diagnose the condition of the fracture whenever changes may have occurred accidentally or as the result of treatment.

Prognosis—When a tibial spine is completely fractured there is little to prevent it from becoming a loose body in the knee joint. Incomplete fracture of the tibial spine will heal with fibrosis if recognized early and if the part is placed at rest.

Fracture of the tibial tubercle heals kindly with no permanent disability when appropriately treated but there will be some increased prominence of the tibial tubercle resulting from this injury.

Fracture of the tibial plateau involving the knee joint is always serious and always produces permanent disability unless promptly and adequately treated. When the fracture is of slight extent and situated so that weight bearing will not increase the deformity it may be that a fracture will heal with the best result if it is not recognized because of the ensuing early use and the lack of fixation. In all other conditions however

this injury produces limitation of motion of the knee joint and deformity of the joint surface and if left untreated results in instability and discomfort. In the more serious injuries with simpler methods of treatment the loss of time in the case of active workers is apt to be considerably over one year whereas with the more active treatment the time loss may be considerably less than a year and the permanent disability negligible.

Fractures of the shaft of the fibula heal without permanent disability in a few weeks. Fractures of the shaft of the tibia alone may result in slight shortening but otherwise heal kindly with the simpler methods of treatment and the x ray film will show good healing in approximately three or four months.

Fractures of both bones of the leg may have a very serious prognosis. Adequate first aid treatment will prevent further damage to the soft parts. Injury to the soft parts is responsible for most of the resulting disability after the bone has healed. Adequate treatment will prevent shortening and deformity. Active workers will need from five to seven months before they may return to duty after this type of injury. When the lower third of the tibia is involved delayed union may result. Non union requiring bone grafting however occurs but rarely.

Treatment—Treatment of fractures of the tibia and fibula should be started immediately. Splint them where they lie is a valuable slogan. The first obligation is to apply proper first aid treatment to prevent any further damage. Since the healing process starts at once it is important to apply first aid treatment which will facilitate the progress of the efforts of nature. The Keller Blake hinged half ring splint should be applied before the patient is moved and the patient should then be transported promptly to the x ray room and the diagnosis completed followed at once by the institution of the form of treatment which is required. If a first aid splint which permits the application of traction is not at hand then flat board splints may be used and should extend well up on the thigh and down below the foot in order to be at all efficient. However any splint which does not permit traction should be considered a makeshift.

Complete fracture of a tibial spine is very

apt to result in the presence of a foreign body in the knee joint which may require removal by arthrotomy. When the x-ray picture shows the fracture to be incomplete a simple posterior splint applied for from four to six weeks will be sufficient. This splint is then removed and only guarded use is made until all symptoms have subsided.

A fracture of the *tibial tubercle* usually is not accompanied by wide separation of the fragments. A felt pad may be placed over the tubercle and held in place by firm adhesive plaster strapping. The adhesive plaster should be crisscrossed over the thigh above the patella and down onto the leg in order to relieve the tension of the quadriceps muscle. A posterior splint should be applied for approximately two months. X-ray studies should be made so as to follow the progress of healing. When wide separation of the fragments occurs an open operation is indicated. The fragment is fastened by one or two bone pegs through the tubercle into the tibia. A hole may be drilled through the tibia and a non absorbable suture passed through the hole and fastened in the patellar tendon just above the tibial tubercle. The treatment is thereafter the same as in the non-operative cases.

A fracture of the *tibial plateau* is always accompanied by hemorrhage into the knee joint and the presence of this blood may tend to keep the fragments displaced. Aspiration of the hemarthrosis is frequently indicated. Application of extension by means of weights and pulleys either on a fracture table or in bed will help to reduce the fracture when it is not too severe. The fragments may be brought into position by extension with weights and then approximated with a carpenter's clamp. The amount of weight required may be 25 pounds or more. Felt padding is then placed on either side of the upper end of the tibia and molded plaster splinting is applied snugly extending from the toes well up on the thigh. There is danger of the development of pressure sores if plaster is applied too tightly and of displacement of the fragments if the splinting is not tight enough. Follow up x-rays must be taken at regular intervals during the first two weeks of treatment and if displacement of the fragments occurs some other method

of treatment should be considered. Approximately six weeks may be required before union is obtained. The apparatus is then removed and treatment directed toward the restoration of the normal function of the knee joint.

Limitation of the motion of the knee is apt to result following this type of fracture. Pain on motion at the knee joint may also persist. The ideal treatment therefore consists of early motion and late weight bearing.

When the fracture of the head of the tibia is extremely comminuted excellent results have been obtained by placing the patient in bed with the extremity suspended from an overhead wooden frame in a Thomas splint with a Pearson attachment which permits motion at the knee joint. A Kirschner wire is passed through the os cruris and an attached extension cord passes over a pulley fastened to the distal end of the Pearson attachment with a 6 pound weight. A second pulley is fastened to the same place on the splint and another cord from the skeletal traction apparatus passes through this pulley and upward to a pulley on the overhead frame here an 11 pound weight is attached. The additional weight upward counterbalances the first weight plus the weight of the leg. Roentgenograms are taken at the end of twenty four hours and the weights are increased or decreased according to the condition revealed. Motion is started at once and continued throughout the treatment. The fragments of the tibial plateau are forced into improved position by the femoral condyles during the passive movements of the knee joint. Roentgenograms should be made at intervals during the first ten days and a satisfactory weight bearing surface should be demonstrated without too much increase in the width of the tibial plateau. There is surprisingly little pain in the knee joint movement when traction is applied in this balanced manner. The patient may be removed from the apparatus as soon as sufficient healing is demonstrated roentgenographically usually after about six weeks. Weight bearing is not permitted for about three months.

Operative treatment may be used to great advantage combined with skeletal traction and early motion as described in the preceding paragraph whenever there is a size

able fragment of the tibial condyle on each side of the fractured upper end of the tibia and when satisfactory reduction and fixation are not obtained by other methods A short curved incision is made just anterior to the head of the fibula beginning at the level of the upper end of the tibia and ending about $1\frac{1}{2}$ inches distally The flap is turned forward and the tibial cortex exposed A drill is passed through the fragments parallel to the knee joint and on the medial side a similar incision is made to permit the drill to come through A $\frac{3}{8}$ -inch bolt is then passed through the drill hole and tightened as much as desired under x ray observation

joint and the stability of the knee joint is but rarely impaired

When the shaft of the fibula alone is fractured it is so well splinted by the tibia that the treatment required is similar to that of an injury of the soft parts Fracture of the tibial shaft without accompanying fracture of the fibula also has the advantage of a natural splint one which prevents over riding The injury to the soft parts may be slight and fixation of the extremity in molded plaster splints including the lower two thirds of the thigh and the foot may suffice The x ray plate may show good formation of callus in six weeks, and all appa

Fig 293—Apparatus for treatment of fracture of the tibia Traction is applied to a Kirschner wire through the condyles and so arranged as to permit flexion and extension of the knee

before closure of the wounds It is not necessary to remove the bolt

It is seldom necessary to open the knee joint to remove loose bodies or injured semilunar cartilages The exploration of the knee joint may increase the surgical risk unnecessarily in many instances and the loose bodies or damaged cartilages can be removed later if they are producing unfavorable symptoms The bolt with washers fastened at both ends has an advantage over screws and nails because of the elimination of the danger of loosening during motion of the knee joint Early motion during treatment gives a less painful and more movable knee

joints may be discarded in approximately three months

Fractures of the shafts of both bones of the leg may be transverse oblique spiral or comminuted When the fracture of the tibia is found on x ray examination to be transverse and displaced the patient should be given ether anesthesia or a spinal anesthetic and the ends of the bone placed in apposition Molded plaster splints are then applied from the toes to the upper half of the thigh When the ends of the tibia are in apposition the fibular fracture requires little if any attention

Occasionally the fracture of the fibula may

be transverse and the tibial fracture of an other variety. In selected cases of this type a small incision is made over the site of the fibular fracture and the ends are placed in accurate apposition. Moulded plaster is then

tempted to reduce oblique fractures under anesthesia followed by the application of plaster cause added injury to soft parts and result in over riding and angulation of the fractured bones. The leg should be elevated

Fig 394—Marked comminuted fracture of the proximal third of the right tibia involving the knee joint with marked distortion of the tibial condyles in a locomotive fireman aged forty five who fell from an engine cab onto a rail. He was first placed in suspension and skeletal traction. After four days of traction the upper end of the tibia was compressed with a carpenter's clamp but after removal x rays showed no improvement. The upper end of the tibia was then bolted and the knee joint was exercised frequently. He was in suspension and skeletal traction. Three and one half months after injury he left the hospital bearing removable molded plaster splints and crutches. The knee was exercised twice daily and would flex to a right angle. Ten months after injury he returned to work as a fireman. Eighteen months after injury he reported having been skating for four hours continuously. The knee joint extended to 10 degrees and flexed to 47 degrees and there was no sign of weakness or instability of the knee joint.

Fig 395—Anteroposterior roentgenogram showing the Kirschner bolt and washers in the upper end of the tibia.

applied and the subsequent treatment is the same as in fracture of the tibia alone.

Fractures of the shafts of both bones of the leg are usually not transverse and should be placed in suspension or at least in elevation and in skeletal traction. Reduction by traction is the only method to be used. At

tempt to assist the part to recover from the disturbance of circulation. With elevation gravity assists the return flow of blood and lymph and diminishes the pathologic changes which result from stasis. The improved circulation hastens the healing process. Skeletal traction by means of a Kirschner wire

TRACTURES OF THE TIBIA AND FIBULA INVOLVING THE ANKLE

Classification —Fractures of the tibia and fibula involving the ankle comprise

- 1 Abduction fractures
- 2 Adduction fractures
- 3 External rotation fractures
- 4 Extension fractures
- 5 Flexion fractures
- 6 T fracture of the lower end of the tibia (compression)
- 7 Atypical fractures

These fractures are in the main caused by indirect violence and are best studied and understood by grouping them according to the direction or application of the fracturing force (Ashhurst)

Fracture of the ankle is sustained when the motion at the ankle joint is carried beyond its normal range External rotation fractures are the most frequent (10 per cent) and with abduction and adduction fractures comprise 95 per cent of all ankle fractures Internal rotation seldom if ever produces a fracture because there is considerable normal excursion of the ankle in this direction a sprain or simple laceration of ligaments rather than a fracture results when the ankle is forcibly rotated internally Furthermore though ankle fractures for the purposes of description and study may be divided arbitrarily into well recognized groups in actual experience some fractures may be observed which result from a combination of several fracturing forces i e not simply from abduction alone but from abduction external rotation and extension (plantar flexion) combined

Anatomy —It is important to recognize that the ankle is a mortice joint in which the astragalus fits into the mortice formed by the lower ends of the tibia and fibula The important and essential structures from a fracture standpoint that maintain this mortice are the internal and external malleoli the posterior articulating surface of the lower end of the tibia (pos

through the os calcis affords the most satisfactory method of reduction The amount of extension weight required for the average patient is 15 pounds The position of the fragments and the amount of extension are obtained by careful measurements by palpation of the tibial crest and by x ray examination

The progress of healing is observed by subsequent examinations with a portable x ray machine and the apparatus must not be disturbed when the x ray picture is being taken The progress of healing should not be tested by attempted movement of the fragments Callus appears normally in the roentgenogram in about thirty days The skeletal traction may be removed as soon as callus appears and skin traction with adhesive plaster and diminished weight may be substituted From thirty to sixty days after injury it may be that healing will have progressed sufficiently to permit the application of molded plaster splints or a walking cast and the patient may be allowed up on crutches

Physiotherapy in all types of fractures described herein should be started early and should be intelligently directed toward overcoming and repairing the pathologic conditions

The extremity is kept elevated to assist the return circulation and diminish swelling Heat is applied to improve the circulation in both directions The patient is instructed to move the toes and the foot frequently Light superficial stroking massage beginning at the toes and working back to the lower part of the thigh may be applied for a few minutes several times daily by nurses This light stroking is designed simply to assist in the removal of the excess fluids in the tissues and must be applied at once and kept up until the swelling has disappeared If physiotherapy is not instituted early and if new inflammatory tissue is allowed to form it is then too late to hope to remove the new tissue The greatest value of physiotherapy after permanent changes have occurred lies in its psychic effect on the patient and the encouragement of voluntary use of the part which at a later date is the best physiotherapy

ROSCOP C WEBB

terior malleolus) the internal and external lateral ligaments and the tibiofibular ligament (Fig 396 a). The internal malleolus lies at a level somewhat anterior and proximal to that of the external malleolus and the internal lateral ligament runs from it to the astragalus and the superior margin of the scaphoid. The external lateral ligament binds the external malleolus to the lateral margin of the astragalus and os calcis. The tibiofibular ligament is especially strong and tough holding the surfaces of contact of the lower ends of the tibia and fibula firmly together. If and when it gives or is torn it permits a dislocation or separation of these surfaces. The posterior articulating margin of the tibia is particularly liable to injury; it is longer and projects farther than is generally supposed (Henderson).

Pathology—When the ankle is forced beyond its normal range of abduction the first structure to yield is either the internal lateral ligament or the internal malleolus. If the internal lateral ligament is not ruptured and holds fast a *transverse* fracture results at the tip, middle or base of the internal malleolus. Occasionally the fracturing force is insufficient to cause further damage. However when it persists in intensity the astragalus and foot, now unrestrained are jammed against the external malleolus. If the tibiofibular ligament gives as is customary, there is a slight separation of the tibia and fibula but more especially there is a lateral displacement of the astragalus and external malleolus throwing a cross strain on the shaft of the fibula above the level of the ligament and a fracture results somewhere in the lower third or at times even

Fig 396—*a*, Diagrammatic illustration of the ankle joint and its ligaments. Note the position of the tibiofibular ligament. *b*, abduction fracture with (1) fracture of internal malleolus; (2) laceration of tibiofibular ligament and separation of tibiofibular articulation; (3) fracture of shaft of fibula and (4) lateral displacement of astragalus. *c*, abduction fracture with intact tibiofibular ligament. Note: (1) Fracture of internal base and (2) fracture of external malleolus near its

Abduction Fracture.—Abduction fracture deserves prior consideration because it is the fracture in which displacement is likely to be greatest, complete and accurate reduction is most essential, and bad or poor results are not sufficiently infrequent.

Etiology—The usual cause of an abduction fracture is a fall on the foot extended laterally away from the vertical axis of the body, but quite frequently, particularly in industrial or athletic accidents the foot may be held firmly and immovable as in a vise and the leg and body weight thrown laterally with the ankle as a pivot, forcing the ankle beyond the normal limits of abduction.

in the middle or upper third (Fig 396 b). On the other hand if the tibiofibular ligament holds a fracture of the *base* of the external malleolus occurs with lateral displacement of the astragalus (Fig 396 c) and there may be a fracture of the lateral margin or external articulating surface of the lower end of the tibia as well. In either case there always results a lateral dislocation of the astragalus to a greater or lesser degree.

In the severe types of abduction fractures, forcible plantar flexion may be present, and a fracture of the posterior articulating surface of the tibia may occur which will permit posterior dislocation of the astragalus or talus as well. Compound or open abduction fracture is occasionally observed. Fractures from abduction may therefore result in:

- 1 Fracture of the internal malleolus.
- 2 Fracture of the internal malleolus or rupture of

the internal lateral ligament with fracture of the fibula (shaft or malleolus), division of the tibiofibular ligament and lateral displacement of the astragalus (Figs 397, 398 and 399).

3 Fracture of the external articulating surface of the tibia or a fracture of its posterior margin; if the latter, posterior dislocation of the ankle may occur

Diagnosis.—The history of the accident and inspection of the ankle will usually suffice to arouse suspicion of a fracture. Pain and swelling about the ankle with inability to bear weight make the diagnosis of fracture fairly obvious. Because of the swelling, deformity may not always be readily detected. In the milder cases local swelling about the internal malleolus may be the only sign. When there has been lateral displacement, the external malleolus with the foot and heel may be definitely abducted and the ankle broadened. When there has been posterior displacement of the astragalus, the foot is plantar-flexed, and the heel is more prominent and farther posterior to the tibia than in the normal foot. Persistent or painful examination is never justifiable, as a roentgenogram is invariably necessary for accurate diagnosis. Simple, gentle palpation over the malleoli and bony prominences should suffice. Local tenderness over bone should be considered pathognomonic of fracture until proved otherwise roentgenologically. To elicit crepitus is cruel and is never indicated. Any swelling about the malleoli, even in the absence of other symptoms or signs, necessitates an x-ray examination; otherwise many fractures will be missed. The exact lesion can be determined only by the roentgenogram.

Treatment.—This fracture should be considered as an emergency, as it brooks no delay in its treatment. A roentgenogram should be taken before reduction is attempted. For transportation and immobilization purposes until reduction can be effected, well padded boot splints or a simple pillow splint will suffice. Morphine should be given for relief of pain.

Anesthesia.—In cases of fractures with but little displacement, no anesthetic is necessary. In the severer types, however, complete relaxation is highly desirable, if not essential. Local anesthesia will suffice therefore only in selected cases. Spinal anesthesia or sodium pentothal is ideal. When these

are contraindicated, general inhalation anesthesia must be used.

Reduction.—When there is only a fracture of the internal malleolus, local anesthesia may be used, and any displacement may be corrected by inversion of the foot, bringing the fragment of the tip up to the base of the malleolus. Molded plaster splints or a short plaster cast with a walking iron is applied for immobilization purposes.

In the severer types of fracture the deformity and the position of the foot and heel

Fig 397—Abduction fracture. Note (1) Fracture of the internal malleolus (transverse), (2) lateral displacement of the astragalus (3) fracture of the external malleolus with lateral displacement. There is no separation of the articulation between the tibia and fibula, & c., the tibiofibular ligament is intact

are guides for the measures required for reduction. The roentgenogram, however, will be the best criterion. While an assistant steadies the leg in the upper third and the knee is flexed to relax the gastrocnemius muscle, the heel and toes are grasped by the operator, and traction is made on the heel to overcome the contraction of the achilles tendon, at the same time correcting any upward proximal displacement of the astragalus. The foot is brought forward, if necessary, to a position of dorsiflexion at a right angle with the long axis of the leg. When

there is backward displacement of the astragalus and fracture of the posterior margin of the lower end of the tibia another assistant should push downward on the lower end of the tibia to obtain complete reduction. The foot is then adducted—maintaining the 90 degree dorsiflexion—to correct the lateral displacement of the external malleolus and astragalus. This adduction should not be as Murray has pointed out an extreme overcorrected position for when the tibiofibular ligament has been torn overcorrection

toward each other so as to correct any remaining lateral deviation of the astragalus and external malleolus and any tibiofibular diastasis. All posterior and lateral displacement should be completely corrected. When this reduction takes place early no great hurry or exhibition of strength is necessary. Gentle steady easing of the fragments back into position is the chief desideratum.

Reduction is maintained by the application of molded plaster splints (Fig 400) or a cast from the toes to the knee in the

Fig 398

NOTE: (1) Laceration of the internal lateral ligament (2) lateral displacement of the astragalus (3) separation of the articulation of the tibia and fibula (4) laceration of the tibiofibular ligament and (5) comminuted fracture in the middle and lower third of the fibula.

Fig 399—Abduction fracture (anteroposterior view). NOTE: (1) Fracture of the internal malleolus (2) lateral displacement of the astragalus (3) rupture of the tibiofibular ligament, (4) marked separation of the articulation of the tibia and fibula and (5) oblique fracture of the lower end of the fibula, the external malleolus being displaced laterally with the astragalus.

will angulate the astragalus against the external malleolus and cause a persisting separation of the tibia and fibula at their articulating margins resulting eventually in painful weight bearing. The inversion should be to the position commonly used to correct a severe grade of flatfoot: i. e. the longitudinal axis of the tibia should pass through the center of the talus. Finally with an assistant holding the foot in reduction direct pressure may be made by the heels of the hands against the malleoli forcing them

severe grades of displacement the flexed knee may be included. The fluoroscope may be used as an important aid in obtaining complete reduction. Often the ankle is so swollen thick or fat and the bones are so superimposed that accurate fluoroscopic vision is difficult. In all cases since complete reduction is so essential a postreduction roentgenogram should be taken both anteroposterior and lateral views. This may be repeated at three to five day intervals for corroboration of the maintained reduction until

union has begun. Occasionally, stereoscopic plates may clear up a doubtful detail.

After-Care.—It is now well recognized that reduction is simply the beginning of fracture treatment and that proper after-

that end. When it seems certain that union has begun and the swelling of the soft tissues has largely receded, the cast is removed and a skin-tight plaster cast applied up to, but not including, the knee. A walking iron or

Fig 400—Actual molded plaster splints (1) Lateral plantar medial or U-shaped No. 1 splint, (2) long posterior shell with foot piece No. 2 splint

care so as to obtain complete restoration of function of the part plays an equally important role in obtaining a satisfactory end result. Though a more or less definite routine must be kept in mind, each case should be conducted solely on its individual requirements. The essential elements of after-care are immobilization that is sufficiently long to obtain union, early active motion, physiotherapy, protected weight bearing and prevention of late eversion of the foot or flatfoot.

If a simple cast is applied for primary restraint, it should be lightly padded about the ankle, and in the severer types of fracture it should be allowed to remain in place for from eight to twelve days, until some union between the fragments has begun. This should not be an arbitrary set-up, and the time should vary with each case. During this period, however, the patient should be encouraged to move his toes periodically as a regular exercise. With this effort there is bound to be contraction of other muscles of the leg beside the extensors and flexors of the toes—even if no movement of the foot is possible, and atrophy and weakness from disuse are thus in part avoided and the eventual return of function is very materially hastened. From the beginning, the patient should be led to realize that he must regain function for himself, the surgeon and physiotherapist can be but adjuncts toward

stirrup may be incorporated so that weight bearing and active use of the extremity may be started (Fig 401). This method should be used with caution, as the weight is not borne by the foot and ankle but by the upper third

Fig 401—Walking iron or stirrup

of the leg. Paralysis of the peroneal nerve and ulcers due to pressure have been known to develop. If a walking stirrup is used, the patient should be kept under close observation. The advantages of this treatment lie

in the early return of function as a result of early maximum voluntary use

When molded splints are used one or both may be cautiously removed daily and guided active motion and light stroking massage begun after from five to ten days. This should be done by the surgeon himself or a competent assistant. The interval of time after reduction before these measures are instituted must vary with the individual fracture. A fetish for early action must not overrule the need for sufficient immobilization.

The cast or plaster splints may be discarded after five or six weeks. Occasionally a posterior shell or splint may be needed for an even longer interval. Daily massage, bathing and regular active exercises by the patient should be instituted and simple weight bearing cautiously allowed. In fractures involving the articulating surface of the posterior margin of the lower end of the tibia weight bearing should be delayed until solid union is certain; this may require ten to twelve weeks. When unprotected weight bearing is permitted there is a great tendency, especially in heavy subjects toward eversion of the foot and actual flatfoot as a result of weakness of the ligaments and muscles because of disuse. Therefore shoes with the inner or medial margin of the sole and heel raised from $\frac{1}{4}$ to $\frac{1}{2}$ inch (0.5 to 1 cm.) should be worn. At times a light brace for the ankle may be necessary or an outside iron with a T strap may be useful. Crutches may be dispensed with as soon as weight bearing is painless and the muscle strength has returned. In cases in which pain is persistent or function is regained slowly diathermy may be added to the physiotherapy armamentarium. *Passive* motion has no place in the after treatment. The early and complete restoration of function hinges largely on the patient's active cooperation in persistent use and exercise of the foot and leg and on the surgeon lies the onus of obtaining full cooperation.

A fracture which involves the internal malleolus alone presents a comparatively minor problem. The time of immobilization may be shortened to three weeks and weight bearing is begun early. In many cases the patient may be permitted to return to work before the completion of treatment pro-

vided no strenuous physical activity is involved.

Tibiofibular Diastasis—Diastasis of the lower tibiofibular articulation occurs especially with fracture of the internal malleolus and lower third of the fibula. The symptoms of fracture may overshadow it. Diastasis may be recognized by tenderness over the tibiofibular joint, widening of the distance between the malleoli and properly taken roentgenograms. Diastasis is very likely when the fracture of the fibula is 2 to 3 inches (5 to 8 cm.) or more above the ankle joint with fracture of the external articulating surface of the tibia.

Recognition of diastasis and early reduction and maintenance of reduction until ligament and fracture healing occurs are imperative or disability from permanent widening of the ankle joint and instability of the distal end of the fibula will result. Reduction is easy unless there is interposition of tissue. When interposition is present open operation through an anterior incision over the joint is indicated. The displaced tissue must be replaced or removed and the tibia and fibula held in position by a screw introduced through a small lateral incision. After union is complete the screw is best removed or painful dorsiflexion may persist. Full weight bearing should be delayed until twelve to sixteen weeks after the accident.

Late Cases—When a patient is presented for treatment a few days or longer after the accident with persistent displacement and deformity the problem of reduction and treatment so as to obtain complete recovery may be exceedingly difficult. Long standing muscle contraction may make manipulatory reduction impossible and even if possible it may be difficult to maintain. Fractures involving the posterior margin of the lower end of the tibia with or without posterior dislocation of the astragalus will tax the ingenuity of the surgeon. Skeletal traction by means of a spike or pin through the os calcis should be tried and is often successful. Overhead traction from the plantar surface of the foot, the weight of the leg and lower extremity acting as counter traction has been used (Gerster). Open operation with internal fixation followed by traction may have to be resorted to.

Prognosis—When a satisfactory reduction

has been effected early and has been well maintained in a patient who cooperates well in the after-care excellent functional results can be expected. The cases of posterior dislocation of the astragalus with fracture of a large fragment of the posterior margin of the tibia may present some late disability due to excessive callus in and posterior to the joint. Fortunately these cases are comparatively rare. When reduction is only barely satisfactory and when it has been performed late in an aged and arthritic person the prognosis should be guarded as some permanent disability is likely to follow or subsequent arthrodesis may be necessary. Furthermore failure of the patient to cooperate sufficiently in the active use of the foot and ankle may lead to some limitation of motion in the ankle which may or may not produce disability.

Malunion.—Malunion results from an unrecognized untreated or improperly treated fracture permits persistent deformity and causes the development of a painful or useless ankle joint and disability of the patient. Open operation for correction of the malposition is necessary usually with some type of arthrodesis of the ankle.

Other Complications.—A persistently painful ankle joint may occasionally result from an abduction fracture even when the reduction is excellent or seems adequate. Murray has suggested that this disability may be due to a persistent tibiofibular diastasis caused by the overadducted or everted position of the foot in reduction angulating the astragalus against the external malleolus. In other instances persistent pain may be due to a post-traumatic arthritis secondary to some focus of infection or metabolic disturbance. Diathermy, elimination of foci of infection and proper diet are essential. A few patients although they complain have no major loss of function and are able to work. When there is considerable disability arthrodesis may have to be considered.

Pott's Fracture.—The fracture originally described by Pott was a severe grade of abduction fracture. The term Pott's fracture in recent years has been very loosely used to indicate all ankle fractures all abduction fractures at the ankle or abduction fractures with lateral and posterior displacement of the talus. Until unanimity of opin-

ion as to its use and definition is reached it fails to be an accurate medical term.

External Rotation Fractures.—*Etiology.*—External rotation fractures are caused by short falls on the foot the foot striking some object such as a curb that twists it in extreme external rotation or else with the foot fixed the leg and body are internally rotated at the ankle twisting the foot laterally.

Pathology.—When the foot is rotated forcibly externally the twist is first transmitted to the lower end of the fibula causing a oblique fracture of its lower third. If the force is continued the internal lateral ligament is ruptured or as a lateral malleolus fracture the tip or middle of the lateral malleolus may be fractured and the fragment displaced anteriorly and laterally. At the same time the rotation of the astragalus is likely to crack off the posterior margin of the lower end of the tibia. Very rarely posterior dislocation of the astragalus occurs from external rotation alone but the forces of abduction extension (plantar flexion) and external rotation are often combined to cause fracture and the characteristic lesions may be associated. There also may be lacerations of the lower tibiofibular articulation or fracture of the external articular surface of the tibia. If this occurs it takes place at the time of fracture of the fibula, and the fibula fracture may then be displaced in the middle or upper third.

The usual lesions are oblique fracture of the fibula oblique fracture of the fibula with rupture of the internal lateral ligament or fracture of the internal malleolus with or without posterior marginal tibial fracture (Fig. 102).

Diagnosis of an external rotation fracture rests on the history of the accident and the roentgenogram. There is usually swelling about the malleoli and ankle but no characteristic deformity and the displacement is seldom more than slight. There will be tenderness over the internal malleolus when it is fractured over the fibula at the point of fracture and posterior to the internal malleolus when the posterior margin of the tibia is involved. The fracture of the fibula may not be revealed except in the lateral roentgenogram when high in the middle and upper thirds it may be missed unless the entire leg is x-rayed.

Treatment.—To reduce the fracture it is necessary to make only slight traction and place the foot in moderate adduction and inversion to bring the fragments into apposition. A cast or molded plaster splints are then applied in this position with the foot in full 90 degree dorsiflexion.

After care follows the outline previously

given for abduction fractures. The cast and splint may be discarded after three or four weeks.

Prognosis is good in a case of simple external rotation fracture. Recovery is complete in from six to eight weeks and work may be resumed by the end of three months—often at the conclusion of treatment.

Adduction Fractures—Etiology—A fall on the foot in adduction or an adduction twist of the ankle though more likely to cause sprain may produce a fracture.

parent. Unless the history of the accident is clear the diagnosis of an adduction fracture rests on the roentgenographic evidence as the lines of fracture are usually characteristic.

Treatment—In fracture of the external malleolus alone or bimalleolar fracture without displacement immobilization in a cast or splints is all that is necessary. Restraint need be employed for only three weeks. If a flail joint is present it may be quite difficult to restore the ankle joint accurately. Fluoroscopic reduction may be an advan-

Fig 402.—External rotation fracture. At left oblique fracture of the lower end of the fibula. At right fracture of the internal malleolus.

Pathology—Forced adduction at the ankle causes first a fracture of the external malleolus at the level of the upper border of the astragalus. The astragalus then impinges against the internal malleolus and, if the trauma is sufficiently great, produces a fracture of its base. The line of fracture extends longitudinally and spirals into the shaft quite different from fracture of the internal malleolus from external rotation and abduction. When this fracture is complete the entire mortise of the ankle is destroyed, and a flail joint may be produced. Clinically two types of adduction fracture are observed: (1) fracture of the external malleolus alone and (2) bimalleolar fracture.

Diagnosis—The evidence of fracture will be swelling about the ankle particularly at the malleoli with tenderness over the fracture areas. Very seldom is a flail joint ap-

parent. As very exact apposition is necessary the foot should be immobilized midway between abduction and adduction and in 90 degree dorsiflexion. Cast or plaster splint should be used for at least five weeks. When displacement of the internal malleolus can not be reduced by manipulation open pegging of the fragment in place may be indicated.

After cure should follow the measures previously described for abduction fractures. The prognosis is good unless the apposition of a bimalleolar fracture has not been sufficiently exact.

Extension Fractures—Etiology—A fall or jump on the extended foot is the usual

cause of an extension fracture. It occurs at times in games such as tennis or basketball from jumping in the air for a ball.

Pathology.—With the foot extended or plantar flexed the astragalus is driven against the posterior margin of the articulating surface of the tibia, sometimes called the posterior malleolus (Destot, Hensler, Cotton), which is broken off. The fracture usually involves the articulating surface of the tibia but very rarely the posterior surface alone. The posterior tibial tubercle may be split off from traction by the inferior posterior tibiofibular ligament. When the force is con-

sprain unless roentgenograms are taken. Though both anteroposterior and lateral views should be made, the lateral roentgenogram will demonstrate the lesion. With posterior dislocation of the astragalus, the prominence and backward position of the heel will be pathognomonic.

Treatment.—Even if there is little or no displacement, it is best to immobilize the ankle in at least 90 degree dorsiflexion. In displaced fracture and especially when some

Fig 403.—Adduction fracture of extreme grade. (1) laceration of the external lateral talar dome. (2) fracture of the internal malleolus at the base with extreme medial displacement and (3) complete medial displacement of the foot and astragalus.

tion. 1 after a posterior talar fracture has occurred posterior dislocation of the astragalus may result (Figs 401 and 403).

Diagnosis.—This type of fracture, if posterior dislocation of the ankle is not evident and unless roentgenograms are carefully taken may easily be overlooked. There may be broadening of the ankle in the anteroposterior diameter and ecchymosis and tenderness on palpation behind the internal malleolus. The foot may be held in extension (plantar flexion), and flexion may be painful. The lesion may be considered a simple

posterior dislocation of the talus is present strong traction on the heel should be made to effect reduction with the knee flexed to relax the gastrocnemius muscle and as much dorsiflexion as possible obtained. If the fragment is large and there is not enough articulating surface of the tibia left intact to hold the talus in place after reduction, open fixation with bone or metal pegs or os calcis pin traction will be necessary. When the articulating surface is involved, there should be at least four weeks of restraint. After care should follow the outline indicated for ab-

duction fractures. Weight bearing should be cautiously permitted and should be avoided for fully ten weeks if the talus is displaced.

Prognosis depends on early and complete reduction of a displaced fragment. Occasionally when there is a large fragment and reduction is satisfactory, excessive callus may lead to some restriction of and pain with ankle motion but rarely will operative intervention be necessary for relief. However in the neglected case when displacement of the posterior malleolus persists and manipulatory reduction is impossible open operation with replacement and fixation of the

tion but a definite diagnosis can be made only from the lateral roentgenogram. It should not be confused however with a displaced internal malleolus. Stereoscopic x-ray pictures will differentiate between the two.

Treatment—Immobilization of the foot in extension or plantar flexion is usually advisable for adequate reduction. As a rule there is but little displacement. Resection of the fragment is rarely necessary.

Compression or T Fracture of the Lower End of the Tibia—Etiology—A fall from a height on the foot or heel in such a way as to force the astragalus against the lower end

Fig 401

Fig 402

Fig 401—Extensive fracture (lateral view). Note (1) Fracture of the posterior articulating margin of the tibia with displacement upward (2) posterior dislocation of the astragalus and (3) long oblique fracture of the fibula in the lower third with marked posterior displacement of the lower fragment.

Fig 402—Extensive fracture after reduction.

fragment will be indicated. For persistent long-standing pain and disability arthrodesis is advisable.

Flexion Fractures—Etiology—A fall on the heel with the foot in flexion (dorsiflexion) is accountable for the rare incidence of this lesion.

Pathology—The weight and force of the fall on the heel drives the talus or astragalus against the anterior articulating surface of the lower end of the tibia and breaks it off.

Diagnosis—Localized pain and swelling over the anterior surface of the ankle will be present with restriction of flexion and exten-

sion of the tibia may cause a splitting or T fracture of the tibia.

Pathology—The impact of the astragalus against the lower end of the tibia may produce numerous lines of fracture or a T type lesion. There is usually lateral and medial displacement of the fragments. There may be a complete laceration of the tibiofibular ligament with the astragalus driven up between the tibia and fibula and the lateral margin of the tibia fractured. A fracture of the fibula in addition is almost always present and very often there is also a fracture of the calcaneus or os calcis or even in the astragalus.

Diagnosis—So much swelling and deformity of the ankle usually results that the exact lesions cannot be determined without an

X-ray picture When shortening of the distance between the plantar surface of the foot and the malleoli with broadening of the ankle is observed this type of fracture may be suspected.

Treatment—Traction on the heel with the knee flexed will usually suffice for reduction followed by bilateral pressure on the malleoli. A cast may not be sufficient to maintain reduction and a traction spike or pin through the os calcis is usually advisable. Reduction may have to be accomplished entirely by os calcis pin traction. Four or five weeks of traction should suffice and no weight bearing should be permitted until at least three months after the accident.

A multiple fracture of this type of injury should make the prognosis for complete return of function guarded since late arthritis may be necessary.

Atypical Fractures—Fractures from direct injury or trauma are mentioned merely for the sake of completeness. The majority of them are quite atypical lesions and must be treated according to individual merits and indications.

FRACTURES OF THE BONES OF THE FOOT

Functional Considerations—When fractures of the foot are considered the highly specialized function of this organ for bearing the body weight must be kept in mind. Its distinctive anatomical feature is the plantar arch which serves as a spring to cushion the impact of locomotion. Weight is transmitted to the ground at three points

the heel, the head of the first metatarsal and the outer border of the foot (fifth metatarsal and cuboid bones). The weight thrust of the body is received by the astragalus from the tibia distinctly to the medial side of the mid axis of the foot and from this there results a tendency for the skeletal tripod to topple over to the inner side with the production of flatfoot. Normally the foot is maintained in a correct weight bearing position by the supporting action of the muscles and ligaments and the strength of the plantar arch is derived from these rather than from the architectural arrangement of the skeleton. When the muscles are weakened from any cause the foot pronates, the arch sags and the foot tires quickly and becomes painful. The chief support of the arch is provided by the tibialis anticus, the tibialis posticus and the long flexor muscles of the toes. Following prolonged immobilization by splints these muscles require special training to restore their strength.

From what has been said it will be seen that certain structural relationships are necessary for proper function of the foot and that any disturbance of these such as may result from a fracture of the tarsal or metatarsal bones is likely to prove disastrous. Therefore in the treatment of such injuries it should be the guiding principle to preserve normal weight bearing lines and to restore as completely as possible the skeletal contour of the plantar arch.

Because of the effect of gravity, the return flow of blood and lymph from the leg is maintained with considerable difficulty. Following fractures of the bones of the leg or foot there is great circulatory stasis and swelling. The swelling is usually most marked in the foot and ankle and is apt to persist for a long period unless special measures are taken to overcome it. Of the various methods to stimulate the circulation early active use of the foot is among the best. This may be obtained by incorporating a steel walking stirrup of the type devised by B. H. in the plaster casing that is commonly employed to maintain alignment after reduction of the fracture (Fig. 406 A, B and C).

When splints have been removed and active movement and use of the foot are permitted the foot should be supported temporarily in correct weight bearing position by

the use of tilted heels, metatarsal bars, arch supports or other braces as indicated (Fig 106 D and F). Active exercises should be prescribed to strengthen the supporting muscles, such as flexing the toes over the edge of a book, picking up marbles with the toes, circumducting the feet inward, upward and outward and rising up and down on the toes.

Diagnostic Principles.—While the experienced clinician can deduce with considerable accuracy the nature of an injury to the bones of the foot, this method is not reli-

tion of the various forces and their probable point of application. The site of injury is to be localized by the evidence of damage to the soft tissues, the location and extent of the swelling, the appearance of gross deformity and the point of maximum local tenderness. Crepitation should not be elicited.

Restriction of the motion of the joint and pain on motion are important signs and point to injury of one or more of the bones that enter into the formation of the articulation. When analyzing the movements of the

The latter is also extended forward for from $2\frac{1}{2}$ to $3\frac{1}{2}$ inch on the inner sole.

able and resort must always be had to roentgen examination to reveal the exact character of the fracture and to prevent possible errors. Since a roentgen examination is to be made in any case, it is important in the clinical part of the examination to employ only gentle manipulations and thus to avoid causing pain and any risk of making the injury worse.

The history is important in arriving at a diagnosis, and one should ascertain the character of the trauma, its severity, the direc-

tion of the various forces and their probable point of application. The site of injury is to be localized by the evidence of damage to the soft tissues, the location and extent of the swelling, the appearance of gross deformity and the point of maximum local tenderness. Crepitation should not be elicited. Restriction of the motion of the joint and pain on motion are important signs and point to injury of one or more of the bones that enter into the formation of the articulation. When analyzing the movements of the foot it should be remembered that the ankle joint normally permits only the movements of dorsiflexion and plantar flexion and that the lateral movements of the foot in inversion and eversion take place at the subtalar and astragalo-cuboid articulations by rotation of the calcaneus and navicular about the fixed astragalus. The small articulations between the anterior tarsal bones provide elasticity but do not permit any demonstrable movement of the forefoot upon the rear foot.

Frequency of Injury of the Bones of the Foot—An idea of the frequency of the various injuries of the tarsal bones may be gained from the following table which is based on a study of 4066 patients with skeletal injuries admitted to the Massachusetts General Hospital between the years 1923 and 1930. The total number of fractures and dislocations was 5436. Fractures of the phalanges and metatarsals are not included in the table as many of these were multiple injuries and could not be classified easily. Fractures of these bones occurred with much greater frequency than those of the tarsal bones.

DISTRIBUTION OF INJURIES OF THE TARSAL BONES

	No. of patients	Per cent of total injuries
Tarsometatarsal dislocation	8	0.07
Fractures of cuboid and cuboid	10	0.09
Fractures of scaphoid	17	0.40
Subastragular dislocations	9	0.09
Total dislocations of astragalus	3	0.07
Fractures of astragalus	17	0.10
Fractures of calcaneus	59	1.50
Total	118	0.61

Fractures of Single Phalanges—Fractures of single phalanges of the toes such as result from striking the toe against a solid object or from the fall of a weight are usually unimportant injuries if not compound and rarely cause more than temporary disability. Bony deformity as a result of the fracture is unusual but care should be employed to prevent the toe from assuming a hammer toe position.

Fractures of a single phalanx may be splinted either by strapping the injured toe to its neighbor or by applying cardboard or felt roll splints. The use of an extra heavy stiff leather sole is an aid to early weight bearing. When the distal phalanx of the great toe is involved the injury may be quite painful largely because of the formation of a hematoma under the nail. Relief may be obtained by drilling the nail and evacuating some of the fluid.

Multiple Fractures of Phalanges and Metatarsals—Multiple fractures of the forefoot are usually produced either by the fall of a heavy weight or by the passage of a wheel over the foot. The trauma is generally severe and distributed over a wide area

so that the phalanges or metatarsals of several digits and not infrequently of all the digits may be implicated. In such injuries the damage of the soft parts and accompanying impairment of the circulation may represent more urgent problems from the standpoint of treatment than the lesions of the bones. The fractures are often compound and the wounds must be cleaned and the devitalized tissue must be trimmed away in a manner similar to that employed in the treatment of compound fractures anywhere. Lacerated tendons should be identified and repaired and the skin edges sutured loosely. The lesser toes are of little functional sig-

nificance and should be amputated when their circulation seems imperiled but every effort should be made to save the great toe.

The amount of bony displacement in the multiple fractures due to crushing injuries is often great and prompt treatment is necessary to secure proper alignment of the bones. This is best accomplished by applying traction to the toes in conjunction with a banjo splint. The latter is a bent wire frame incorporated in a plaster casing. The toes offer too small a skin surface to make adhesive traction effective and consequently direct skeletal traction by means of small wires or needles passed through the distal phalanges must often be used. The wires are connected to the banjo frame of the splint by rubber elastic bands.

This apparatus brings about realignment of the bones and maintains position while at the same time permitting exposure of the wound for dressings. Union of the fractures requires from four to six weeks but weight bearing with the aid of crutches cannot usually be permitted before the end of from eight to ten weeks. Massage to improve the circulation and active mobilization of the

toes should be begun as early as the state of the wound permits

Fracture of the Tarsal Scaphoid—Fracture of the tarsal scaphoid is uncommon but the injuries are almost always identical. The fracture is produced by an impact against the ball of the foot usually by a fall in which

open up the space occupied by the scaphoid bone while at the same time digital pressure is exerted on the dorsally displaced fragment. Following reduction the foot must be fixed by the application of a plaster casing in the position of equinus. Fixation may be removed at the end of six weeks but weight

the person lands with his weight on the forefoot. The force is received on the metatarsal heads and transmitted backward to the anterior tarsal bones and the scaphoid situated at the apex of the arch is crushed between the head of the astragalus and the

bearing should not be permitted until the end of from ten to twelve weeks.

Fracture of the Astragalus—Fracture of the astragalus is a rare and very disabling injury. The most common variety involves the body of the bone or the junction

Fig 408.—Fracture of the tarsal scaphoid. A Tracing showing the typical dorsal displacement of the superior fragment. B the same case after closed reduction and fixation in a plaster in the equinus position.

cuneiform bones. There results a comminuted compression fracture of the scaphoid with the dislocation dorsally of a large superior fragment.

When the patient is seen early reduction can usually be accomplished by manipulation under full anesthesia. The forefoot must be forced into extreme plantar flexion to

of the body with the neck and consists of a vertical split extending downward in the frontal plane from the superior articular surface to the subastragalar joint. There may be more or less comminution.

The fracture is usually produced by striking on the foot after a fall from a height, the impact of the ground and the weight thrust

of the body coming into opposition in the region of the astragalus where it arches forward from the calcaneus to the scaphoid. The trauma is severe and gross deformity usually results, the large posterior fragment being usually dislocated backward out of the ankle joint mortise and also frequently rotated inward or outward as well. Owing to the thin envelop of soft tissues about the ankle joint these structures are often torn and the injury is rendered compound. If not compound in the beginning it may easily become compound by necrosis of the overlying skin from pressure of the unreduced fragment beneath.

The treatment of this injury nearly always necessitates operative removal of the astragalus. Owing to the fact that the posterior fragment is usually devoid of blood supply there is little chance of a good result

importance arises in certain cases of injury to the foot as to whether a small triangular piece of bone revealed in the lateral roentgenogram as lying posterior to the body of the astragalus represents an actual fracture or is only the os trigonum, an anomalous bone formed by the failure of a separate center of ossification to fuse with the body of the astragalus which is present in about 10 per cent of normal persons without causing symptoms. In answering this question it is important to note whether or not the signs of injury are localized in this region and also to have roentgenograms of the normal foot for comparison. When a similar shadow is present in the opposite foot it is probably not a fracture.

Fractures of the Calcaneus—On account of their frequent occurrence and their disabling effect fractures of the calcaneus

Fig 409.—A complete fracture-dislocation of the astragalus. A, Roentgenographic appearance immediately after injury. Note the posterorotary dislocation of the body of the astragalus. The neck of the astragalus is still in situ. B, appearance one year after astragalectomy.

from its replacement, even when this can be accomplished without danger of infection, as it is apt to undergo aseptic necrosis and later crumble under the superincumbent weight of the body. When the fracture is compound the fragment is generally so soiled that its replacement would be unsafe. Astragalectomy does not give a normal foot but when performed properly yields a useful and pain-free foot. Removal of the astragalus should be combined with careful debridement and extensive drainage of the wound when the injury is compound. A plaster casting should be applied from toes to thigh with the knee flexed, the foot well displaced backward under the tibia and in a position of equinus. Fixation is necessary for from eight to ten weeks and a brace should be fitted when weight-bearing is to be permitted.

A question of considerable medicolegal

deserve to be ranked as the most important bony injuries of the foot. They constitute between 1 and 2 per cent of all skeletal injuries and industrial liability insurance companies are in agreement that they give rise to relatively greater disability than almost any other variety of fracture.

A fracture of the calcaneus is generally caused by a fall from a height, the person striking on one heel. The height does not need to be great and in older persons such an injury may follow a fall of 4 or 5 feet. Occasionally it may be caused by a twist of the foot. The fracture is bilateral in about 10 per cent of the cases. It is rarely compound. In falls of considerable distance it is frequently associated with other skeletal injuries, the most common being compression fractures of the vertebrae, fractures of the shaft of the femur or fractures of the pelvis.

The fracture generally involves the body of the calcaneus but occasionally the apophyseal portion of the tuberosity alone is implicated a fragment to which the tendo achillis is attached being avulsed and pulled upward by this muscle. Fractures of the body of the calcaneus may be divided into crush fractures and fissure fractures. The crush fractures are characterized by extreme comminution of the entire calcaneus and by gross deformity. The fissure fractures are also comminuted but less so than the true crush fractures and one or two chief fracture lines can usually be distinguished. These are generally in the form of the letter V with the limbs extending upward from

The diagnosis of fracture of the calcaneus can usually be made from the history of a fall followed by inability to bear weight on the foot and pain in the region of the heel. On examination there is swelling about the heel local tenderness and occasionally a normal mobility. Deformity can often be recognized in the form of shortening and elevation of the heel. The ankle motions are free, but the subastragalar movements are limited and painful.

The roentgen examination should include lateral anteroposterior and plantar views of the foot. The plantar view is made with the film under the heel and the tube directed in such a manner that the rays pass obliquely

Fig. 410.—Tracings of roentgenograms of normal and fractured calcanei showing alterations in the relationship of lines prolonging their superior surfaces. A Normal B slight defect C moderate defect D very marked defect.

the plantar surface of the calcaneus and spreading to enclose the posterior articular facet which is generally depressed or tilted.

There is usually considerable displacement which presents three characteristic features. The posterior process of the heel is displaced upward as a result both of the impact against the ground and of the pull of the gastrocnemius muscle. It is also driven forward so that the heel is shortened. Because the weight thrust through the tibia falls to the medial side of the longitudinal axis of the heel the foot tends to pronate under the impact of a fall and since the calcaneus is fractured when the heel is in eversion the posterior process is usually displaced laterally

downward and forward through the ankle. The normal foot as well as the injured one should be included in the examination in order to show the degree of displacement. The extent of the deformity may not be appreciated unless two lines are drawn on the film with a ruler: the first uniting the posterior superior tubercle of the calcaneus and the posterior tip of the articular facet and the second the anterior superior tip of the calcaneus and the posterior articular margin (Fig. 410). Normally these two lines intersect each other at an angle and the degree of the angle registers the oblique axis of the posterior heel process. In case of fracture this angle is much increased and if there is considerable deformity the lines may fail to

intersect and instead become parallel. The restoration of the normal angle is one of the chief objectives of efforts at reduction.

Failure to correct the displacement in fractures of the calcaneus gives rise to several different types of disability. The flattening and outward deviation of the heel disturbs the weight bearing mechanics of the foot with resulting pronation or flattening of the arch and symptoms of weakness and strain. The outward displacement of the calcaneus may lead to bony impingement against the lateral malleolus causing pain and limitation of motion. The fracture may produce so much irregularity of the superior articular facets as to limit function and cause chronic synovitis and pain. Lastly the displacement may give rise to abnormal

plantar surface of the foot (Fig. 411 A). A weight of 15 pounds is usually sufficient but more may be required. After the traction weight has been connected a special pressure clamp is applied to the body of the calcaneus in the transverse diameter and the bone compressed strongly. Bohler has devised a special clamp for this purpose which is molded to restore the normal anatomical contour (Fig. 411 B) but a carpenter's C clamp serves almost as well. Layers of felt are applied between the clamp and the skin. The compression should not be maintained for more than a few minutes. The traction force tends to prevent recurrence of the deformity after the clamp has been removed.

The leg should be left in this apparatus for from two to three weeks at the end of

Fig. 411.—A. Apparatus for reducing a fracture of the calcaneus by skeletal traction (after Bohler). B. Special clamp designed by Bohler to correct lateral spreading of the calcaneus.

bony prominences on the plantar surface which may become painful pressure points.

The treatment of the fracture must aim to remove all of these possible causes of disability and the solution lies in correction of the deformity. This can be accomplished when the patient is seen soon after injury. General or spinal anesthesia is necessary. Skeletal traction is applied to the heel by means of a Kirschner wire inserted through the posterior process of the heel. A Thomas splint bent so as to allow 45 degrees of flexion at the knee is applied to the leg and suspended from an overhead frame. The leg is supported in the splint by strong canvas strips which extend distally to just above the heel. The spreader of the Kirschner wire is connected to a weight by a cord passing over a pulley, the line being adjusted so that it bisects the 90 degree angle formed by the longitudinal axis of the leg and the

which time a plaster casing is applied. The Kirschner wire may be removed through openings cut in the casing after the plaster has hardened. Because the wire passes directly through the seat of fracture there is considerable risk in leaving it in place more than three or four weeks. When applying the plaster it may be desirable to fix the ankle in a position of equinus in order to relax the gastrocnemius muscle and reduce its deforming pull on the calcaneus. Fixation of the foot in plaster should be maintained for a period of eight weeks. Baking, massage and exercise of the foot and ankle may be started after the removal of the plaster but weight bearing should not be permitted before the end of twelve weeks as the cancellous bone remains soft for some time and some of the correction might be lost.

While the chief aim in the treatment of fractures of the calcaneus is the correction

of bony deformity it must be admitted that it is often impossible on account of extreme comminution to achieve this objective as completely as in the case of many other skeletal fractures. Particularly is this apt to be the case in securing restoration of a smooth articular surface with the result that many of the patients continue to complain of pain even after the fracture has healed. The pain is aggravated by use of the foot and is worse in those persons whose work requires much standing or considerable physical effort. Examination generally dis-

of the subastragalar joint will be necessary to relieve the pain. This operation does not generally impair the usefulness of the foot as motion is preserved at the ankle joint and a certain amount of hypermobility develops in the midtarsal and anterior tarsal joints which compensates to some extent for the motion that is lost. As a matter of fact few of these patients have any appreciable motion of the subastragalar joint before operation and in any case the diminution of motion is but a small price to pay in return for the boon of relief from pain. Care must

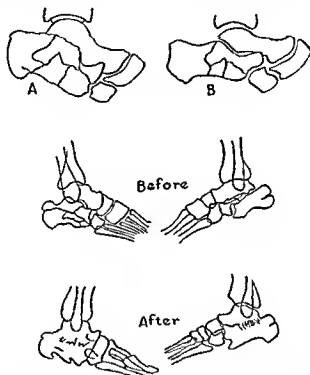

Fig. 410.—(A) lateral fracture of the calcaneus (A) before and (B) after subastragalar fusion. Before fusion Note the marked displacement. After fusion The patient can stand and walk all day without pain.

closes that the pain and tenderness are localized below the external malleolus that the lateral movements of the foot are considerably restricted and that pain is produced whenever the attempt is made to manipulate the foot into a position of inversion. The roentgenographic examination reveals irregularity of the superior articulating surface of the calcaneus and narrowing of the joint space.

These are the signs of a chronic degenerative arthritis resulting from the traumatic changes in the joint and an operation to remove the cartilage and secure ankylosis

be taken during and after the operation to preserve the normal weight bearing lines of the foot. The operation of subastragalar fusion is so frequently required in cases of severely comminuted fractures of the calcaneus involving the articular surface that in certain recent cases it may be the better part of wisdom to anticipate the occurrence of future trouble by fusing the joint from two to four weeks following the fracture thus restoring the patient to usefulness at the earliest possible moment.

PHILIP D. WILSON

BIRTH INJURIES AND FRACTURES AND EPIPHYSEAL INJURIES IN CHILDREN

General Considerations—Although injuries of bone in children are very similar in most respects to those which occur at an older age there are certain peculiarities and differences that should be noted.

Fractures may take place in utero or during the process of delivery and so be present at birth. The marked elasticity and the thick periosteum of growing bones tend to produce certain types of fracture such as the incomplete or greenstick fracture and the subperiosteal or buckling fracture. In children the epiphyses from which the bones grow may become separated from the shaft by trauma with possible interference with the growth of the bone. Fractures at certain places in the skeleton such as the middle of the clavicle the lower end of the humerus both bones of the forearm and the shaft of the femur are more frequent in children than in adults.

The prognosis in a case of fracture at this age is better in general than it is in later life. The good osteogenetic power of growing bone and the relatively smaller size of children's bones tend to result in strong and rapid healing in most cases and non union is rather infrequent. Of great importance is the tendency of growing bone to correct angulation and other deformities. Shortening of a considerable extent may be made up in the process of growth. On the other hand epiphyseal injuries in some cases may lead to premature union of the epiphysis and the shaft with a permanent shortening in the length of the bone. When this occurs in one of the bones of the forearm or the leg a serious deformity may result.

INTRAUTERINE FRACTURES

A fracture of the bones may occur in utero and may be evidenced in the newborn by swelling and deformity at the site of fracture. The roentgenograms in such a case show signs of callus formation indicating that the fracture was present for some time before birth.

The condition may be due to (1) trauma to the abdomen of the mother especially in cases of oligohydramnios in which the small

amount of amniotic fluid is insufficient to protect the child in utero or to (2) osteogenesis imperfecta a congenital condition in which the bones are abnormally brittle and predisposed to fractures from slight trauma. The majority of intrauterine fractures result from this congenital fragility of the child's bones which is a hereditary condition in about 15 per cent of the cases. The fractures are usually multiple and the ribs and long bones are most frequently involved. Union takes place rather slowly with little callus formation and considerable deformity in most cases.

When evidences of intrauterine fractures are discovered at birth it is presumptive that the child is afflicted with osteogenesis imperfecta and milk the most careful handling will prevent the occurrence of additional fractures. For several months the infant should lie constantly on a soft pillow and for a year or two after that should be kept fastened to a Bradford frame. No attempt to correct any deformities should be made until the child is older for fear of producing more fractures.

Although the cause of osteogenesis imperfecta is unknown and no particular treatment seems to benefit the bone condition the child should be placed under the best hygienic conditions of rest food and sunshine. Cod liver oil and calcium preparations should be administered to increase, if possible the lime content of the bones. Parathyroid extract does not seem to have any favorable influence on the condition.

Intrauterine Amputations—In rare instances the distal portion of an arm or of a leg of a newly born infant may be missing. The end of the affected member resembles the stump following a surgical amputation and may even show a granulating wound if healing was not completed before birth. The condition may be limited to the loss of one or more fingers but it may involve the major portion of a limb. In some cases the affected member may show one or more congenital furrows on the skin due to long pressure from bands that have caused scar formation in the subcutaneous tissue. This congenital deformity is usually associated with a condition of oligohydramnios which permits the umbilical cord or an adventitious amniotic band to become ensnared about

the limb. The resulting strangulation causes interference with the growth of the distal portion of the limb or even amputation.

The process of amputation probably occurs in the early months of gestation when the limbs are quite small and the missing part is usually not discovered but occasionally it has been found in the lochia. Where the constriction from the cord or band has

the child's bones more often it is (2) the result of trauma when delivery is difficult because of a contracted pelvis or malposition of the child.

In many instances the obstetrician may feel or hear the bone break but more often the condition is not discovered until some time after birth when attention is drawn to the part by pain, swelling and deformity. A

Fig. 413—Roentgenogram of newborn child showing multiple intrauterine fractures.

not been sufficient to cause an amputation the distal part of the limb may be atrophied and deformed with rudimentary fingers or toes.

Obstetrical Fractures—This term is used to designate all fractures of the bones of a child which occur during delivery. The etiological factor may be (1) some constitutional disease such as osteogenesis imperfecta which causes abnormal fragility of

roentgenogram will usually show a transverse fracture very often of the subperiosteal type with angulation but no displacement of the fragments. The bones most frequently affected by obstetrical fractures are the clavicle, humerus and femur. The skull may be broken by the obstetrical forceps.

The treatment of these fractures should consist of obtaining union by the simplest and most comfortable fixation dressing. The

outlook for a satisfactory anatomical and functional result is good. Any deformity tends to disappear rapidly in young growing bones.

Clavicle—Fractures of the clavicle usually occur in the middle third as a result of efforts to bring down an arm in a breech presentation or to free a shoulder in a difficult head presentation. The usual signs of this injury are tenderness, swelling, angulation and disuse of the part. A satisfactory dressing in such a case is a smooth and well applied Velpert's bandage which will hold the forearm in flexion with the shoulder fixed well back. Before this bandage is applied the skin should be powdered and covered with sheet wadding wherever the arm touches the chest wall. Fixation for two weeks is usually sufficient to obtain union.

The *humerus* is usually fractured at the junction of the middle and lower thirds of the shaft during manipulation of the arm in delivery. The usual signs of fracture are present but displacement of the fragments is infrequent. The simplest treatment for this fracture is fixation of the arm in a slightly abducted position. A wedge shaped axillary pad extending from the axillary fold to the elbow is fastened to the chest wall with adhesive plaster. A small apposition splint made of wooden tongue depressors bound together in corset fashion with adhesive plaster is fastened about the upper arm if there is much displacement of the fragments. The arm is then fixed over the axillary pad with adhesive plaster with the forearm fixed around the base of the splint. A snug bandage which holds the arm and shaft firmly against the chest wall completes the dressing. After three weeks the union is usually strong enough to permit the arm to be released.

The *femur* is affected most frequently in obstetrical fractures. The break usually occurs in the middle third of the bone and results from obstetrical manipulation of the thigh. The accident is usually recognized immediately but if not attention is directed to it by the marked anterior angulation that generally takes place at the site of fracture. These fractures of the femur in newborn infants are treated best by either of the following methods.

1 *Fixation in the Fetal Position*—The

thigh is usually flexed with the knee in extension thus bringing the front of the thigh against the abdomen with the front of the leg resting on the chest and the foot at the clavicle. After the skin has been powdered and a towel has been placed between the opposing skin surfaces the limb is fixed in position by a soft bandage. The dressing should be opened daily so that proper attention can be given to the skin. Fixation in this position is well tolerated by infants and tends to correct the anterior angulation.

2 *Fixation in Overhead Traction*—The child is fastened to a Bradford frame and a Buck extension apparatus is attached to both legs so that they can be held suspended at right angles to the body by overhead traction. A corset splint made of wooden tongue depressors is bound around the injured thigh and just enough weight applied so that the hips are barely lifted from the bed.

Immobilization by either of these simple methods for three weeks is usually sufficient to obtain firm union.

Traumatic Separation of Epiphyses—During the period of bone growth up to the age of twenty years the epiphyses may be injured.

Etiology—Boys in the second decade of life are affected most often probably because of the strenuous character of their exercise at that age. Constitutional diseases such as scurvy, rickets and syphilis which affect the growth cartilages may be predisposing factors but most of the injuries occur in healthy boys. The trauma is usually a ligamentous strain caused by hyperextension or hyperflexion with abduction of the limb accompanied by torsion as when a leg is caught in a revolving wheel. The injury may occur during birth from traction on the limb with twisting. A direct blow may be the causative factor in some instances in which epiphyses such as the external condyle of the humerus or the greater trochanter of the femur are injured. In all cases the violence is of such a severe character that it would tend to produce a dislocation rather than a fracture in adult bones.

Pathology—The epiphyses of the long bones are involved most often especially those at the lower end of the radius the

lower end of the femur and the upper and lower ends of the humerus. The other epiphyses of the long bones are affected less often and those of the short and flat bones only occasionally. The lesion in most cases is a partial or total separation of the epiphysis from the diaphysis. An accompanying fracture of the epiphysis is very rare although it does occur occasionally at the lower end of the radius femur and humerus but the epiphyseal separation is always the principal lesion.

Epiphyseal separations may be divided into three classes according to the position of the line of separation.

Fig 414—Separation of the epiphysis of the external condyle of the humerus with periosteal stripping

1 *Division of the epiphysis in which there is a clean separation of the epiphyseal cartilage from the diaphysis.* The cartilage remains attached to the epiphysis with no osseous tissue adherent to it. This form occurs only in very young children and is rare.

2 *Juxtaepiphyseal separation occurs when the line of separation passes through the osseous layer at the end of the diaphysis and small particles of osseous tissue remain adherent to the epiphyseal cartilage.* This is a frequent form of epiphyseal separation especially in the first decade.

3 *Pre Epiphyseal Fractures*—The line of separation passes through the spongy bone of the diaphysis near the epiphyseal line and definite fragments of the diaphysis are broken off and remain adherent to the cartilage. This form occurs most often in older children in whom ossification has advanced to the extent that the epiphysis is almost united to the diaphysis.

The degree of displacement of the epiphysis depends on the direction and force of the violence and the particular epiphysis involved. *Incomplete* displacement is much more frequent than the *complete* type especially in younger children (Fig 414).

Stripping of the periosteum from the shaft usually occurs if there is much displacement as the periosteum remains attached to the epiphysis. Dislocation of an epiphysis from its joint relations is very rare but it may occur occasionally at the upper or lower end of the humerus. An accompanying injury to blood vessels and nerves may be caused by pressure or laceration from the end of the diaphysis and occurs most often in separations at the lower end of the humerus and femur. A compound separation of an epiphysis is a highly serious injury which often results in osteomyelitis and arrest of growth or gangrene, which may necessitate amputation.

Symptomatology—The clinical picture of an epiphyseal separation is more like that of a dislocation than a fracture. The injury is usually produced by a severe wrenching force. *Pain and tenderness* are most marked over the epiphyseal line. A false point of motion and deformity are evident in most cases in which there is much displacement. Discoloration from ecchymoses is usually very definite. Crepitus when it can be elicited is important because it is of a soft crunching character quite different from the hard bony crepitus of a fracture. Inability to move the limb will be present if there is much displacement. Swelling of the soft parts is usually apparent and distention of the joint is marked if the injured epiphysis is intra-articular. When the displacement is slight or partial the only evidence of injury may be localized pain and tenderness and the clinical picture will be similar to that of a sprain.

Diagnosis—In children and adolescents when the accident is due to a twisting force

and the clinical signs point to an injury to the end of a bone, an epiphyseal separation is probably present. A differential diagnosis should be made if possible to exclude a sprain fracture or dislocation. A roentgenogram is of considerable value except in very young children, in whom the epiphysis is not

fractures. Any displacement of the epiphysis should be accurately reduced with as little trauma as possible under the guidance of the fluoroscope, and the part should be properly immobilized. In order to preserve the function of the injury epiphysis, it is important to institute treatment at the earliest

Fig. 415—Partial separation of the lower epiphysis of the radius

sufficiently ossified to cast a shadow, or in cases in which the displacement is so slight that it cannot be seen (Fig. 415).

Prognosis—In every case of injury to an epiphysis the prognosis should be guarded because there may be some interference with the growth of the bone. Fortunately, in most instances the epiphysis continues to function normally, especially if any displacement has been carefully reduced and proper treatment instituted promptly. However, in a certain few cases the injury will cause a premature union of the epiphysis to the shaft or interfere with the nutrition of the conjugal cartilage sufficiently to alter the normal growth of the bone.

Arrest of growth which may be temporary but is usually permanent will probably follow in such cases. The degree of the resulting deformity will depend on the age of the patient and the influence of the injured epiphysis in the normal growth of the bone. Injuries of the upper epiphysis of the humerus or the lower epiphysis of the radius or femur are most apt to produce growth deformities. When the growth of one of two parallel bones is affected, the normal growth in the uninjured bone will cause a marked deviation of the hand or foot. Lengthening of the bone instead of shortening may occur in rare instances when the injury exerts an irritating influence on the epiphyseal cartilage and causes an excessive growth of bone.

Treatment.—In general the treatment of epiphyseal separation is similar to that of

possible moment. Under general anesthesia replacement is not difficult in most cases and the parts tend to remain in position after reduction. A suitable splint which will not injure the soft parts is applied as a retention dressing. Massage and passive motion may be started after ten days. In most

Fig. 416—Old complete separation of the lower epiphysis of the femur requiring operative treatment.

cases prolonged immobilization is not required, and fixation dressings can usually be discarded after two or three weeks.

Open operation may be necessary in intra-articular epiphyses such as the head of the femur, radius or humerus to reduce the displacement and fix the epiphysis in place on the diaphysis. Operative treatment is indi-

cated also in other cases when reduction by the closed method is impossible because of muscle pull or the intervention of soft parts and in old neglected cases if the displacement has remained unreduced for several weeks (Fig 416). Interference with the circulation of the limb from injury to the blood vessels may lead to ischemic palsy or gangrene and necessitate urgent surgical treatment. Arrest of growth or excessive growth in one of two parallel bones may require resection of a portion of the shaft or excision of the cartilage of the longer bone in order to overcome the deformity.

COMPOUND FRACTURES

The basic principles in the management of a patient with a compound fracture are as follows:

- I Treatment of shock and hemorrhage.
- II Prophylaxis and treatment of wound infection.
- III Accurate reduction and complete immobilization. In actual practice these three are associated at the same time and disaster may be the result of neglect of any one of them.

I Treatment of Shock and Hemorrhage—Shock and hemorrhage are frequently grave and attention must be devoted to them first.

1 Drugs—Morphine is always indicated except in head injuries. In the instance of

multiple injuries including the brain it may still be given if accompanied by extreme

2 Heat—Body temperature must be maintained in some way but this must be done with judgment and the patient not kept bathed in perspiration with loss of body fluids.

3 Control of Bleeding—In most instances a pressure dressing is all that is necessary. The tourniquet has been grossly misused. An ineffective tourniquet has often caused serious loss of venous blood which ceases as soon as the tourniquet is removed. Tourniquets should be of a type which can be loosened easily and definite orders should be issued as to the frequency of loosening. Usually this should be done every half hour.

4 Traction—The major function of traction fixation as a first aid measure before the patient is transported is to prevent or relieve shock and hemorrhage. Traction on a broken extremity relieves pain by putting muscles at rest and it diminishes extravasation by causing relaxed fibers again to exert pressures on tissues within it. Traction also limits further injury due to the churning about of fragments thereby preventing increased shock and increased hemorrhage.

5 Fluid Replacement—This is supremely necessary at the earliest possible moment. Loss of plasma from the blood is the early sign of shock, not a lowered systolic pressure. Whether whole blood, plasma, serum or normal saline solution is required has now been fairly well standardized by accurate laboratory tests. (See section on Shock and Collapse.)

6 Evaluation of the Patient's Condition—Multiple injuries are frequent in patients with compound fractures. One must try to determine immediately and without added trauma or exposure whether injuries to the brain, spine, chest, abdominal viscera and kidneys are present. Are a probable source of shock and hemorrhage require postponement of further treatment of the compound fracture or require first consideration when the patient's condition will allow of any further procedure?

II Prophylaxis and Treatment of Wound Infection—This should commence at the scene of accident and should be continued concurrently with the treatment of shock and hemorrhage.

1 *Dressing*—The wound should be covered if possible with a sterile dressing. The use of antiseptics irrigations etc. is not to be advised.

2 *Traction*—Traction fixation before moving the injured person from the site of accident is important in the prevention of infection. Whether the fracture is compounded from within or without the tissues are contaminated. Not to put the muscles at rest and therefore to allow the fragments to move about increases the area of contamination.

The wounds of compound fractures are of three types and in all of them traction fixation is to be employed.

Type 1 If the compound fracture is one in which there is merely a wound and if there is no known soiled bone inside the wound the traction splint will not only protect the underlying tissues but will keep the bone from coming out through the opening and getting dirty or spreading dirt around in side if such exists.

Type 2 If the compound fracture is one which has been produced by some sharp object that penetrated the extremity and if the sharp object was dirty causing contamination of the wound the application of traction will keep the contaminating organisms from being spread around underneath the skin. Everyone should insist on the application of fixed traction in either of these cases.

Type 3 If the fracture is such that the end of the bone comes out through the skin and becomes dirty a more difficult decision must be made. One fears the result of carrying soiled bone back into the soft parts as may happen under traction. This type of fracture is not common and is an injury extremely serious as regards both life and limb under any circumstances. The patient must be operated upon at the first possible moment. I believe that in order to transport the patient without danger of added trauma from the fragment of bone that remains inside the wound or without added contamination of the soft parts the use of traction is proper.

3 *Debridement*—Wounds are contaminated at first not infected and this contamination is in large part removable. With laboratory control of the requirements of

the circulatory system one does not need to wait possibly beyond the optimum time before debridement on account of shock but can treat shock or hemorrhage and debride the wound all at the same time. Without chemotherapy we set an arbitrary limit of six hours from the time of accident within which debridement may be done with expectation of success. But the danger of infection is greatly lessened if it can be done in one to two hours instead of six hours. In some instances when the injured person does not reach us until between six and twelve hours have passed debridement may still be tried although with much less hope of success for contamination will usually no longer be limited to the surface. After twelve hours debridement is contraindicated. Operative intervention then must be limited to enlarging the wound, leaving open deep pockets and removing gross foreign bodies. With the use of sulfanilamide or calcium penicillin locally at the time of injury or of one of the sulfonamide drugs orally from the time of injury to the time of operation the period during which only contamination may exist and infection may not have set in has been found prolonged in many instances to seventy-two hours or more.

4 *Serums and Drugs*—Unless the injured person is known to be immunized by toxoid tetanus antitoxin should be given immediately in all cases in which there is possible clothing or soil contamination. Repeating it is to be considered if there is any further operative intervention after the first week. If the injured person is known to have been immunized by toxoid more than three months previous to injury 1 cc. of tetanus toxoid should be injected if available. Otherwise tetanus antitoxin should be administered. In severe crushing wounds in which the growth of anaerobic organisms is likely a primary dressing with zinc peroxide as recommended by Meleney is useful.

Gas gangrene serum as a prophylactic and also in treatment doses on the slightest suspicion of the presence of gas gangrene is advisable. The parenteral use of penicillin and the oral use of sulfadiazine are valuable following debridement. With limited experience thus far the local use of penicillin solution commenced with the dressing of the wound after debridement seems worth

while but the value of the sulfa drugs locally in the e cases is questionable

5 *Closure of the Wound*—No debrided wound is free from bacteria. All we can hope for is that the body resistance will cope with the remainder without the development of a purulent process. The means most likely to invoke infection is to permit tension in the wound as serum is thrown out. Therefore is a general procedure these wounds should not be sutured primarily even with a drain but left wide open. Primary suture has been successful many times but with its general use there are more instances of grave infection, osteomyelitis, amputation and death.

6 *Drainage of the Wound*—All pockets should be kept open. If their sides are allowed to fall together secretions may pocket off making ideal media for growth of bacteria. Petrolatum properly applied with or without gauze and with or without an antiseptic acts as an effective drain. It must reach every part of the depth of the wound preventing dead spaces. The wound must never be packed tightly and it should not be dressed until profuse discharge or objectionable odor makes it necessary. This saves the energy and time of the patient, the doctor and the nurse.

7 *Immobilization*—Without complete immobilization muscular action may change the site of contamination or infection at any moment. A non padded plaster encasement with or without internal fixation or two pin traction comes nearest to furnishing complete immobilization of the soft parts in order to prevent or allay infection. This does not include a window in the plaster at the site of the wound which destroys even pressure and allows edema and stasis of fluid with increased danger of infection.

8 *Treatment of Established Infection*—If emergency traction, debridement, serums and drugs, drainage of the wound and immobilization have not been adequate or successful and infection is established the principles are the same as in the care of any soft part infection early and of osteomyelitis later with this difference—in spite of treatment of the infection one must bend every effort to preserve reduction and immobilization of the fracture. The two problems cannot be separated. Whatever else is

done for *grs* bacillus infection adequate surgical drainage remains the important factor.

9 *Evaluation of the Wound*—In the prophylaxis and treatment of wound infection whether early or late the virulence and extent of the contamination and the severity of the soft part damage must be considered as well as the elapsed time. More contamination will usually take place in a fracture compounded from the outside than in one compounded from the inside although both unquestionably demand debridement. Major blood vessel damage may be such that the part distal to it cannot survive. The muscle damage may be such that it is evident immediately or at the time of debridement that a useful limb cannot possibly be obtained. With these factors in mind primary amputation should sometimes be done to save life or prevent prolonged morbidity, with a useless extremity as a final result.

III *Accurate Reduction and Complete Immobilization*—We have considered saving the patient from death due to shock and hemorrhage and from death or loss of limb from infection. It is necessary also to aim for proper union of the fracture at the same time.

1 *Traction*—Application of traction fixation at the site of accident makes reduction simpler in the operating room. Traction should be continued under all circumstances until the patient is on the operating table and in some form even there.

2 *X ray*—Unless hemorrhage or the time factor makes it impossible a ray examination should be carried out before debridement.

3 *Reduction*—In many instances adequate debridement will result in visualization of the line of fracture and perfect reduction can be obtained by sight rather than by palpation. Its accuracy is important as regards both infection and union. Reduction should not be delayed until infection is controlled.

4 *Maintenance of Reduction*—Complete immobilization is necessary if debridement is to be effective in preventing infection. If the fragments in an oblique fracture are slipping slightly each day the likelihood that infection will become established is increased. Unquestionably immediate rigid internal

fixation of the fragments is the best answer. Lather the Carrel technic or petrolatum gauze without closure of the wound can be used in the presence of plates and screws. Internal fixation must be rigid. The metal may be removed if infection sets in or when bony healing has progressed sufficiently. Although ideal it is questionable whether this method should be used in cases of compound fractures by surgeons inexperienced in the rigid internal fixation of simple fractures. Without this experience or in an instance in which plate screws etc seem contraindicated the second choice is two pin traction with one (or more) pin or wire proximal and the second one distal to the fracture. Both are incorporated in the plaster of paris encasement usually after machine reduction. Again it is questionable whether this method should be used in the case of compound fractures by surgeons not experienced in the use of the apparatus in simple fractures.

Third in order of effectiveness is the non-padded plaster encasement. It presents grave dangers and offers less security but is probably safest of the three for the surgeon who treats only an occasional case.

Skeletal traction with a distal pin only. Russell traction in cases of fracture of the femur adhesive plaster traction padded plaster of paris encasement and splints of any material do not measure up completely to the requirements for immobilization. Conditions arise in which any one of them may have to be the method of choice in the individual case. If there is a question of adequate circulation of the part or of the thoroughness of the debridement or of the virulence of the contaminant a closed plaster encasement should not be used for several days at least but some form of traction and suspension should be used instead which allows observation of the wound and the surrounding tissues.

5 Evaluation of the Fracture—In some instances it may be found that an extensive area of bone or even the entire knee joint or ankle joint has been completely blown away. Immediate amputation must be considered rather than at best a prolonged convalescence with probably a useless limb resulting.

THE OPERATIVE TREATMENT OF FRACTURES

Indications for Open Reduction of Fractures—The indications for open reduction of fractures are positive in only a few cases typically in fractures of the olecranon and of the patella with separation of the fragments. The intrusion of soft tissue between the ends of the fragments is another absolute indication for operative intervention and nerve injury complicating a fracture being treated operatively at the same time. A large proportion of other fractures should not be operated on without first trying methods of closed reduction and fixation. As a general principle if it is impossible to reduce a fracture to a place where a good functional result can be reasonably expected then it is permissible to operate. The skill and equipment of the surgeon are always a factor in the decision. In this special line of work the reports of percentages of open reductions vary from 4.5 to as high as 45.5 per cent.

Every fracture is a law unto itself and its treatment must be considered individually. Open operation should be avoided if a satisfactory functional result can be obtained without it but if it is necessary to operate the simplest possible method should be used with a minimum of foreign material. However no case should be allowed to progress to a point where callus formation has started before it is decided that open operation is necessary because the disturbance of bone-forming cells at a time when they are beginning to be active is frequently fatal to a continuation of their activity. Therefore if closed reduction will not suffice after a week or ten days of trial and if there are no contraindications such as systemic disease, circulatory disturbance or senility the operation should be performed. No fracture should be operated on if there is any active infective process in any part of the body because a blood borne infection will probably occur. No fracture should be operated on if there are abrasions on the skin which cannot be made perfectly clean and sterile. Systemic diseases which contraindicate other surgical procedures also preclude the open reduction of fractures.

Compound fractures* should not be subject to open operation unless the wound is sufficiently large after debridement to allow a clear view of the fracture. It may at times be permissible to lever the bones back into position and immobilize the fracture thus rendering further manipulation unnecessary. However no foreign body of any kind—metal ivory beef bone or autogenous bone—should be introduced to maintain the fragments in position and no holes should be drilled through the bone. A fracture which is compound is always potentially infected and osteomyelitis and non union will occur if this becomes an actuality. In a large percentage of cases the first treatment of a compound fracture determines its future. The wound should be covered immediately with sterile compresses while the surrounding skin is cleansed with soap and water washing away from the edges of the wound. Then with sharp sterile instruments preferably a scalpel and a pair of tooth forceps the traumatized margins of skin should be cut off every bit of questionable muscle fascia and fat should be removed and active bleeding should be stopped. The edges of the wound should be retracted and loose pieces of bone and any debris at the bottom of the wound should be removed. It is the writer's custom then to wash the wound and the skin around it with ether which does not destroy tissue and is non irritating. When the ether has evaporated the wound is closed with through and through sutures care being taken that there is not too much tension.

Thorough debridement is the most important part of this procedure with the exception of cleansing the skin and tissues around the wound. There will always be considerable oozing from such a wound. The patient's temperature should be watched carefully, a blood count should be taken frequently and the wound should be inspected within twenty four hours by the surgeon. If infection becomes apparent the stitches should be removed and the wound opened wide for drainage. Strong antiseptics should not be used, a sharp knife does not traumatize and untraumatized tissues have marked resistance to infection whereas traumatized

tissue and blood clots offer a fertile field for bacterial growth.

Choice of Time for Operation—It is fairly generally agreed among surgeons that the choice of time for operative intervention in cases of fracture is from five to ten days following occurrence. This gives sufficient time for the tissues to recover from trauma and for the blood clot to organize and yet not sufficient time to allow callus to form. The swelling is less and bleeding at operation is less if this rule is followed. It also permits healing of abrasions in the neighborhood of the fracture. This does not mean however that no attempt should be made in the interim to maintain the fragments in as good position as possible. The less muscle contracture which is permitted the easier the operation and the more easily the fragments can be held in alignment after the operation.

Fracture of the clavicle comes to open operation less frequently than probably any other fracture of the long bones. Healing is rapid non union is rare and a functional result is not difficult to obtain with closed methods. (See section on Fractures of the Clavicle.)

Fracture of the Humerus—*Fracture of the anatomical neck of the humerus* is rare indeed. It is extremely difficult to reduce and hold in reduction and in most cases this should not be attempted by closed methods. The joint should be opened and the head replaced and fixed to the shaft. It is important that the cartilaginous surface of the head is not damaged. Time then will tell whether the head will unite to the shaft or go on to progressive absorption. In the latter instance its removal will be necessary.

Fracture Dislocation of the Head of the Humerus—A fracture of the surgical neck complicated by dislocation of the head is practically always an operative case. No leverage can be put on the head through the shaft by the usual methods of reduction. However if the head has not protruded completely through the capsule it sometimes may be forced back by direct pressure from the anterior inferior surface. It is a difficult surgical procedure to reduce the head without damaging the cartilaginous surface and it will be found that there are usually a number of comminuted fractures

* See also the section by Kennedy on Compound Fractures.

in the head running down toward the shaft and out toward the tuberosities the whole mass of bone being held together by the capsule of the joint. The method of fixation which is most satisfactory is to drive an ivory or bone screw from the shaft into the largest fragment of the head. The arm should then be maintained in a position of 60 degrees of abduction with the elbow on a plane with the anterior chest wall also a balanced position between extreme internal and external rotation should be sought.

The Shaft—Improper immobilization is perhaps the most frequent cause of non union in fractures of the humeral shaft. Operative treatment then of course is indicated. Mid shaft fractures are not infrequently associated with injury of the radial nerve and because of this open reduction is often necessary.

Supracondylar fractures in children are frequently confused in the mind of the student with fractures of the lower end of the humerus into the elbow joint. These fractures in children do not enter the elbow joint and in the writer's experience are practically never operative cases except as the result of malunion which should never occur because these fractures are not difficult to reduce.

Fractures of the condyles of the humerus except the internal epicondyle do involve the elbow in children as well as in adults. They should be reestablished in perfect position or if this is impossible they should be operated on and fastened in absolute anatomical alignment. It is not difficult to hold such a fracture in position with an absorbable screw or peg and this is the method of choice. Care should be taken not to damage the articular surface during operation. T or Y fractures involving both condyles are difficult to reduce by any method. Yet it is extremely important that they be reduced perfectly so that the axes of both condyles are normal. The closed method may be attempted but frequently open reduction will be found necessary. Contractures in the capsule of the elbow joint and the rapid contracture of the biceps muscle make the prognosis for a freely movable elbow unfavorable. In addition callus forms with facility and its exuberance may be the cause of a true bony block in the joint.

Fracture of the Radius—The Head—Frequently in fracture of the head of the radius in adults if the head is badly comminuted and displaced it should be removed being cut off at the neck so that there is no contact between the outer condyle of the humerus and the radius. In children however the head should not be removed but every effort should be made to replace the fragments in good position and maintain them so. If this is not done the growth from the proximal epiphysis will be distorted and a change in the carrying angle of the arm may occur with the possibility of loss of flexion and extension.

The Shaft—The radius must be considered as an extension of the hand upward just as the ulna is considered as an extension of the arm downward. The radius is concerned with motions of dexterity in the hand and the ulna with motions of strength in the elbow. Their function therefore is important and if it is impossible to reduce a fracture of the radius or the ulna or both so as to permit normal motions of the hand and elbow such fractures should undergo operative reduction. In many cases it is extremely difficult to maintain the bones of the forearm in reduction because of the cross pull of the pronators and supinators and because of the extreme activity of the muscles of the forearm. Unless proper splinting and sometimes traction are maintained after reduction angulation will take place even after open reduction in spite of firm internal fixation. This holds true in simple fractures of the radius as well as fractures of both bones of the forearm. Distal fractures in the radius are sometimes difficult to maintain in position because of the almost exactly transverse pull of the pronator quadratus which causes an angulation of the radius toward the ulna and when they cannot be maintained in reduction by closed methods they should be fastened securely by internal splinting. Fractures of the lower end of the radius into cancellous tissue are practically never operative cases because they can be molded into position better by closed methods.

It must be remembered that any shortening or deformity in the radius affects the radioulnar joint therefore it is important that the relationship between the radius and the

ulna is accurately reestablished so that no deviation in rotation of the fragments or change in their long axis is allowed as this will cause loss of dexterity in the hand.

Fracture of the Ulna—Fractures of the olecranon if there is any separation of the fragments are always operative cases. The pull of the triceps cannot be controlled by any method other than a direct union between the triceps tendon and the lower fragment of the ulna. Therefore the upper fragment should be fastened securely to the lower fragment and in the writer's experience malleable iron wire serves as the strongest form of union. Moderate motion may be started within a few days without fear of separating the fragments.

Fractures of the shaft of the ulna do not present a difficult problem if the radius has not been fractured and if the head has not been removed otherwise such fractures are extremely difficult to hold in position without constant traction. The lower half of the shaft of the ulna is quite small and fragile but in it are attached strong and very active muscles. The upper half of the shaft is much stronger but not infrequently fracture of its upper third occurs in combination with a forward dislocation of the head of the radius. In such an event the radial head usually cannot be held in position without flexion of the elbow beyond a right angle and in this position it is almost impossible to hold the ulnar fracture. If this is found to be true after a conscientious trial of closed methods it will be necessary to fix the fracture of the ulna firmly by some method of internal fixation adaptable to the case—in oblique fractures a screw of absorbable material in transverse fractures some form of plate.

Fracture of the Carpus—The operative treatment of scaphoid fractures has been the subject of much recent discussion. Non-union which is frequent leads to serious disability especially in workmen who must handle tools or bear heavy weights. Murray using a bone graft placed longitudinally through the bone has obtained better results than those reported by any other operative method. This applies particularly to fractures which occur in a single line more or less transverse through the middle third of the bone. If the fracture is comminuted removal of the bone through a posterior in-

cision with great care not to injure any of the other bones with which this one articulates gives the most satisfactory result.

Dislocation of the lunate bone is much more frequent than fracture. Davis favors the replacement of the bone. It is frequently impossible to reduce the dislocation by non-operative methods and the operative method involves prying it back into position by instrumentation. Since it is covered on four sides by cartilage more or less damage is inflicted on the cartilage and in the writer's opinion frequently leads to the development of a traumatic arthritis also as the circulation to the bone is for the most part cut off by tearing of the dorsal ligament at the time of dislocation absorption is likely to occur. If replacement cannot be accomplished either by open or closed method excision is the only alternative.

Fracture of the remaining carpal bones is extremely rare and open operation in their treatment usually consists of excision. This of course is resorted to only after attempts at closed reduction have failed.

Fracture of the Metacarpals—It should not be necessary to operate for the primary replacement of fragments in fractures of the metacarpals and phalanges since they can be maintained in position by proper traction and splinting.

Fracture of the Pelvis—As a general rule fractures of the pelvis are not operative cases. Separation at the symphysis complicated by fracture of other parts of the pelvis ring however frequently requires operation because circular pressure cannot be maintained without further displacement of the other fractures. Usually they can be held by some form of suture and here again malleable iron wire has proved most satisfactory.

General Fracture of the Acetabulum and **Dislocation of the Head of the Femur**—In central dislocations of the head of the femur which are the result of fracture of the acetabulum the head of the femur is sometimes driven entirely through the acetabulum and lies inside the pelvis. It is impossible to reduce this by any closed procedure and reduction by operation is extremely difficult. The approach must be from the inside of the pelvis because the fragment which lies around the base of the head of the femur and acts as a locking device prevents

the head from being moved laterally and out of the acetabulum and it must be pried back in order to permit retraction of the head. After it has been moved so that the head can be brought into normal position the fragment of the acetabulum must be forced back into as near normal position as possible in order to have a smooth socket to articulate with the head. When this is accomplished the simplest method of maintaining the head in a normal position and of preventing displacement of the fragments of the pelvis is to pass Kirschner wire or a Steinmann pin through the trochanter of the femur and to establish lateral traction which should continue until the fragments have firmly healed in place.

Fracture of the Femur—Intracapsular Fracture of the Neck of the Femur—There is probably no fracture in the body which results in non union so frequently as does intracapsular fracture of the neck of the femur. Indications for operation in this injury are in open dispute among authorities at present. The Whitman method of closed reduction and maintenance has been the accepted practice for many years but it has resulted in union in only 40 per cent of the cases. Murphy advocated the use of a large nail driven through the trochanter into the neck in the long axis of the neck fastening the head. Smith Petersen advocates a special nail with three flanges to maintain the head in proper apposition to the neck. Albee has advocated autogenous bone nails. The writer has used ivory screws and ivory nails of large size and while these means of internal fixation after the fracture has been properly adjusted help to maintain the desired position of the fragments they do not promote union. The lack of bony union is not entirely due to faulty alignment of the fracture but apparently is due to lack of circulation in this part of the bone. Therefore anything which has as its aim simply maintenance of position of the fragments will not promote or give assurance of assisting union. This fracture occurs usually in elderly persons and the reconstructive processes at this period of life are not so active as in younger persons. In old ununited fractures Whitman advocated removing the head removing the trochanter by an incision made from the base of the neck downward and out

ward rounding off the upper end of the shaft and placing it in the acetabulum and retreating the trochanter lower down on the shaft. This certainly would not be indicated in a fresh fracture. Brackett advanced the operation of rounding off the end of the trochanter hollowing out the head of the femur and placing the end of the trochanter in the hollowed out head. Neither of these operations is adaptable exactly for the repair of fresh fractures. The writer has taken certain features of both operations and designed an operation which is adaptable to fresh fractures of the neck of the femur reestablishing close contact between the shaft and the head and thereby allowing the circulation to be reestablished from the shaft to the head and maintaining anatomical relations.

Extracapsular Fracture of the Neck of the Femur—In the vast majority of fractures of this type it is unnecessary to consider operation. Non union seldom occurs but mal union is frequent as a result of improper reduction and immobilization.

Intertrochanteric fractures can practically always be reduced by closed methods and held in reduction without operative intervention. No fracture heals more kindly. It becomes united much more rapidly than does a fracture of the shaft which involves the cortical bone. However occasionally the lesser tuberosity is fractured completely free from the shaft, and it may be necessary to bring this down into position by a suture and hold it to the shaft.

Subtrochanteric fractures necessitate open operation when the long arm of the lower fragment which can be controlled cannot be brought into sufficiently good alignment with the upper fragment which cannot be controlled. Any internal splinting in this fracture must be firm but no matter what internal splinting device is used traction must be maintained during the period of convalescence or the great group of adductor muscles will angulate the fragment at the point of fracture and break or bend the immobilizing apparatus.

Shaft—Many operations which are performed for reduction of fractures of the shaft of the femur seem to the writer to be unnecessary and could be avoided if sufficient traction were applied and the pull of the muscles both as to angulation and as to

over riding were considered. The indication for operation is the impossibility of reduction by any closed method such as skeletal traction, skin traction and traction through the ligaments of the flexed joint. If operation is necessary, traction must be maintained afterward no matter what method of internal fixation may be used.

Supracondylar fracture of the femur should be operated on when it is impossible to reduce it by closed methods. This should include a trial with Kirschner wire through the condyles with the knee flexed at an angle of 90 degrees or more. The quadriceps bursa extends upward over the fracture and should not be entered at the time of operation but should be carefully displaced forward. The fracture if oblique may be held by a screw or nail of absorbable material which is put through at an angle so that it will not act as a pivot on which the fracture can be angulated.

T and I fractures and intra-articular fractures of the lower end of the femur are frequently difficult to replace in anatomical position but this must be done if the function of the knee joint is to be preserved. Therefore they should be considered operative cases within the first ten days after fracture unless reduction can be accomplished by closed methods.

Fracture of the Patella—Fractures of the patella are always operative cases if there is any degree of separation between the fragments which indicates that the ligaments are torn. Arbitrarily one may say that any fracture in which there is more than $\frac{1}{4}$ inch of separation is an operative case. Here again as in a fracture of the olecranon the muscles attached to the upper fragment constantly displace that fragment upward and there is no means of holding the fragments together without tying the upper fragments to the lower one. There have been many methods devised for doing this. A circular suture of chromic catgut or wire around the patella with a suture of the ligament or capsule or suturing the fragments together with silk wire or kangaroo tendon has been used. However cancellous bone does not tolerate a great deal of strain consequently there is rapid atrophy of bone or cutting out of bone cells as a result of pressure. Again the writer's preference is for

malleable iron wire because of its strength and pliability and non-irritating quality. If the patellar tendon is attached firmly by strong material to the quadriceps tendon considering the patella only as an obstruction in the way of this suture much better results will be obtained than by actually suturing the bone and the fractured surfaces of the patella are absolutely in contact and are held so by the wire which passes through from the patellar tendon to the quadriceps tendon.

Fracture of the Tibia—Intra-articular fractures of the tibia include splints into the joint with separation of the weight bearing surface of the upper end of the tibia and bumper fractures. The latter have drawn their name from the fact that they occur when a person is struck by an automobile bumper, the external condyle being driven down against the upper end of the tibia, the internal lateral ligament holding the upper end of the tibia and the downward crushing throwing the knee into a valgus position. These fractures are difficult to realign by any closed method and frequently result in extremely disabling deformities. They are also difficult to operate on with the expectation of establishing complete function of the knee. The most satisfactory results have been reported by Cubbin.

The difficulty lies in the fact that there is actual crushing down and dissolution of bone cells in the upper end of the tibia on its lateral weight bearing aspect. The upper fragment must be pried loose from the lower fragment into which it is impacted and frequently comminuted; it must be raised to the normal level and the interspaces filled in with bone taken from some other part of the body or from the longer fragment. It is a difficult surgical feat but the fracture should be operated on by a skillful surgeon within the first week or ten days following the accident.

Fractures of the shaft of the tibia usually may be reduced by closed methods if they are seen within twenty-four to forty-eight hours. The interposition of soft parts, however, or the entangling of long oblique spikes of bone in the muscle renders it necessary to reduce them by operation. Operations on the tibia are not considered so difficult as operations on other bones because of the

superficial anterior surface which lies immediately under the skin. The surgeon must not be misled however by the ease of operation because maintenance in reduction especially in oblique fractures is not as easy as it might seem. If the fracture is oblique absorbable nails or screws may be used and the leg may be immobilized in plaster. If the fracture is transverse it is usually not necessary to operate and if in rare cases it does become necessary the abutment of the square ends against each other is sufficient to maintain alignment if dressings and immobilization are properly applied.

Fractures of the distal end of the tibia such as Pott's fracture usually are not operative cases. However it is advisable to fix the internal malleolus if the internal malleolus is fractured exactly on a level with the articular surface of the lower end of the tibia and it is impossible to reduce the fracture by inversion of the foot without displacing the internal malleolus toward the medial surface which would bring the articular surface of the astragalus into contact with part of the fractured surface on the lower end of the upper fragment. A single absorbable peg is driven through the tip of the malleolus into the shaft of the tibia the rest of the fibula being held in position by inversion of the foot in the usual position of reduction.

Split fractures of the lower end of the tibia occasionally occur as the result of a fall from a height one portion of the tibia being displaced forward on the astragalus and the other backward. It is necessary to bring the fragments back into position by open operation in order to reestablish the smooth weight bearing surface. If this is not exact a painful ankle joint will result. If the fragments can be wedged together and held by a screw immobilization of the ankle may be neither necessary nor advisable establishment of early motion produces a better result.

Fracture of the posterior lip of the tibia with backward displacement of the astragalus on the tibia is common. When manipulation will not bring this fragment down into absolutely perfect position and dorsiflexion of the foot will not maintain it in this position operative treatment is necessary. Because of its inaccessibility it is difficult to handle and the fragment of the posterior

lip is frequently comminuted and so small that no retention apparatus can be placed through it. It will be found that molding it down into shape and maintaining strong dorsiflexion will hold it in position but this flexion must not be relaxed for a moment else the fragment will slip up and the foot will have a tendency to dislocate backward on the tibia. The position must be maintained until union is complete.

Fracture of the Os Calcis—Fractures of the os calcis are not operative primarily. It is necessary however to cut the tendo achillis in most of these cases to prevent its effect of upward displacement on the posterior fragment of the os calcis and permit molding of the comminuted fragments and breaking up of the impaction which always occurs. Old fractures of the os calcis which result in loss of function of the joint and pain on walking are considered under the head of malunited fractures.

Fracture of the Astragalus—Fractures of the astragalus frequently are primarily operative if the fragments cannot be brought into anatomical position. A transverse fracture of the astragalus through the neck with the upper fragment free in the joint or displaced backward or forward must be accurately replaced if a functional joint is to be expected. If this replacement cannot be made by a closed procedure it should be done by operation but no retention apparatus should be inserted because all surfaces of this fragment are covered by cartilage except the fractured surface and a replacement with the foot held in dorsiflexion will suffice to maintain the fragments in position.

Fractures of the other tarsals metatarsals and phalanges should not be considered from an operative standpoint. It is not necessary to operate on them to obtain reduction and there have been no better results following operation than following non-operative methods.

GENERAL CONSIDERATIONS

Requisites of the Surgeon.—The operative treatment of fractures should be undertaken only by a surgeon who is a mechanic and by that I mean not only the type of skilled mechanic who feels with tools but a calnet maker who can do fine joining and carving. He must be able to do this under most trying circumstances where the parts are practically inaccessible to

instrumentation. He must have a thorough knowledge of the anatomy and physiology involved as well as the pathology. The surgical technic requires the highest degree of asepsis because bones have less resistance to infection than almost any tissue in the body, and should infection occur in a bone there ensues a long period of disability, frequently with deformity and loss of function which cannot be corrected by any form of surgery. Therefore the entire procedure of operation must be carefully planned in advance although at the same time an open mind must be maintained so that the technic can be changed if necessary, to meet the requirements of the individual case.

There can be no fixed rule for operation of any type of fracture. Since no matter how extensive an equipment the specialist may have at hand many times none of it can be made to fit or hold the fracture his mechanical ingenuity therefore must be called into play. In spite of their strength bones must be handled with as much delicacy as other tissues and most infections occur as a result of trauma to the parts during operation rather than from any other cause. The resistance of bone can be lowered by the use of crushing force as easily as that of soft tissue. Therefore the requisites of the surgeon who prepares to operate on fractures must be: First, he must be a doctor and as such consider the welfare of his patient above everything; that he has a doctor's conscience and because of the dangers attendant on open reduction will not operate if less serious measures will bring about a satisfactory result. Second he must be well grounded in anatomy, in physiology and in pathology. Finally, he must be a surgeon who combines delicacy of handling of tissues with surgical judgment and mechanical skill and the ability to devise ways and means for obtaining a good result in spite of many difficulties.

Requisites of Equipment, Operating Room and Assistants.—Surgeons of bones and joints because of its highly mechanical nature requires extensive special equipment. Fine mechanical work cannot be executed without proper tools and the man who attempts it cannot expect a satisfactory result. Motor-driven instruments are important. Facility in handling these tools can be acquired on wood and in the animal laboratory and when one is expert in their use much more skilful work can be accomplished. Further the time of operation can be reduced considerably. It is impossible to enumerate all the equipment necessary for this type of surgery but let it be said that bones vary tremendously in size and strength and the instruments used to manipulate them must also vary. The instrument used on a femur cannot be used on an ulna, because it does not fit, the instrument used on cancellous bone cannot be used on cortical bone so that a multiplicity of equipment is necessary to meet the requirements of various conditions and various bones.

The set up and personnel of the operating room is equally important. Assistants, interns and nurses must be experienced in this work and must feel that they share in the responsibility. Team work is important especially in operations involving the transplantation of bones because here two fields are prepared and movement from one to the other must take place with meticulous care. Details of operating room equipment

must be provided in advance so that there will be no possibility of contamination. It is the writer's custom to have two entirely different sets of instruments one for each field and nothing goes from one field to the other except the graft which has been removed.

The application of linen relegated by many surgeons to the intern or even to a nurse is a highly technical procedure and should not be entrusted to inexperienced hands. The surgeon should supervise the application of linen in all its phases or else do it himself having in mind the position in which he wishes to maintain the part and the position in which most of the work can be best accomplished.

Preparation of the Patient in the Ward and in the Operating Room.—The field or fields of operation should be prepared in the ward prior to removal of the patient to the operating room. This consists in proper shaving of the parts, cleansing with green soap and ether and the application of a large alcohol dressing. In working near the hand or foot care must be taken to shorten and clean the nails and free the interdigital spaces of any infectious material. It is the custom of some surgeons to carry out this sterile preoperative preparation two or even three times but if it has been carried out thoroughly on the day before operation once is sufficient.

When the patient is brought to the operating room the dressings are removed and again the skin is scrubbed with ether followed by iodine preferably a weak solution which serves as a guide by coloring the skin over the area to be cleansed so that no spot can be left untouched. This is followed by alcohol in from 70 to 90 per cent solution in sterile water until the iodine is entirely removed. Care must be taken to see that the ether does not run up a member which is being held off the table and soak into the covering of the operating table, where it cannot evaporate readily because this may result in a painful ether burn of the skin. Sterile towels are usually tucked under the leg and into the groin or under the arm and into the axilla depending on the field of operation and are removed before the linen is applied.

Anesthesia.—In operations involving fractures it is usually not necessary to have such a profound state of anesthesia as in abdominal operations and the milder forms of anesthetic may be used. Nitrous blocking, nitrous oxide, ethylene or avertin may be used with success in selected cases. The most satisfactory anesthesia in the writer's opinion is avertin 70 to 80 rag per kilogram of body weight given in the patient's room. This acts as a sleep-inducing drug and a tranquilizer and ethylene is administered during the operation. This combination gives complete analgesia and is not followed by the nausea which frequently accompanies ether anesthesia. The writer has not used ether for several years in the operative treatment of fractures.

Requisites of Ward Attendants and Postoperative Care.—The care of fractures in the ward, operative or non-operative is fully as important as the reduction. Traction should be maintained with the amount of weight necessary to hold the fragments in position and counteract the displacing pull of the attached muscles. It should be impressed on all attendants that pain should not follow operative reduction of a fracture if properly reduced and held in proper position.

tion it is practically painless. Pain is the red flag and if a patient complains of pain following reduction of a fracture the cause should be investigated. Rather free oozing between the closing sutures is not infrequent where considerable dissecting has been necessary to free the ends of a fractured bone. This oozing from the bone cannot be stopped although active bleeding can be controlled by the use of bone wax. Almost invariably considerable bleeding is evident on the dressings. The dressings should be applied in such a way that the outer dressings can be replaced without interference with the retention apparatus and the dressings close to the wound should not be disturbed because the oozing will stop within twenty-four hours and becoming dry will seal the wound effectively.

Methods of Internal Fixation.—Many methods of internal fixation have been devised and advocated. As stated before one cannot be prepared to meet all the emergencies that may develop without having at hand many forms of mechanical equipment. Since there has been used since the early days of open reduction of fractures. Silver wire cannot be depended on for fixation braided or twisted phosphor bronze wire is very flexible and in a case in which little fixation is necessary may serve to steady a fracture. However if it is necessary to use wire as in fractures of the olecranon or patella malleable iron wire is most satisfactory and ordinary bailing or stove wire is tolerated by the tissues as well as any other type. No metal whether it be wire or plates, will maintain a strong hold on bone for more than two weeks. No matter how tightly the metal is applied at operation subsequent bone atrophy about this foreign body will cause it to become loose.

Steel plates advocated by Sir Arbuthnot Lane, have been much abused by both instrument makers and surgeons. Instrument makers have made them of unreliable steel which bends easily and surgeons have used them under circumstances where they were not in keeping with the best surgical judgment. They should form a part of the armamentarium of every surgeon engaged in operative reduction of fractures but should never be used where they are in any contact with the skin and should ordinarily be buried deep under the muscles.

Ivory plates beef-bone plates and machined screws are frequently applicable. The plate of ivory is set into the bone as a key in a key way and is held to each fragment by an ivory nail or peg driven through the cortex the plate having been completely drilled through from one surface of the bone to the opposite. The bone plate devised by Boughton and Eck is screwed on the surface of the bone and can be used in lieu of the Lane plate. It is also applicable in some places where an ivory plate cannot be used. Ivory or bone machined screws are useful especially in oblique fractures where several can be put in through the obliquity to join the two fragments. Both these materials are absorbable after a considerable time. Ivory is 100 per cent stronger than beef bone and will support more strain but neither ivory nor beef bone should be trusted to bridge too great a gap. They should not be set across the middle of the medullary cavity but should be placed in such a way that so

far as possible their course passes through cortical bone.

Autogenous bone grafts are not usually required in fresh fractures but constitute the most satisfactory means of retaining position and assisting union in ununited or malunited fractures. The difficulty of mechanically accurate application of the graft renders this a greater surgical undertaking than other methods of fixation.

Metal Nails and Screws.—The writer does not advocate the use of metal nails and screws but in certain cases this may be the only way to meet a mechanical as well as a surgical problem. All these methods necessitate the use of drills, taps and sometimes circular saws; therefore, mechanical skill is required in their application.

Wedging of the ends of the fragments sometimes is the most satisfactory method of maintaining apposition. Whether or not this can be done depends on the condition of the ends of the fractured bones. If the fracture is comminuted it cannot be done but if more or less wedged or fish tailed at one end it is sometimes possible. Great care must be taken however to see that the line is maintained in exactly proper position after the wedging is accomplished because the assistant who holds the member by changing the position of his body, may disarrange the fragments even after the wound is closed. It is usually more satisfactory to put through a small ivory or bone screw or nail even though it be very oblique to steady the fragments and to be sure they do not slip out of position.

PHYSICAL MEDICINE IN FRACTURES

The chief principles of fracture treatment, according to Wilson are (1) restoration of anatomical form as soon as possible after injury (2) maintenance of alignment and fixation of the fracture during the period of healing and (3) institution of measures to overcome the circulatory disturbances and to maintain and develop function beginning at the earliest possible moment after injury and continuing until complete recovery is obtained.

The intelligent use of physical therapy is not by a technician but by the surgeon. It is the only way to accomplish the third principle. To overcome the circulatory distur-

ances heat massage and exercise are used, to develop function exercises and occupational therapy are indispensable.

Physical therapy in the treatment of fracture does not require complicated and expensive apparatus. The physical agents of the greatest use in the treatment of fractures are heat massage and exercise. Of all therapeutic adjuncts these are the simplest, the most flexible, the most easily obtainable and least expensive. Their therapeutic value is largely dependent on the skill with which they are administered.

Heat—Good local circulation which is essential for repair of injured tissues is increased by local application of heat. Heat should be applied for at least one-half hour three or more times daily.

To apply heat locally radiant heat from an electric lamp baker is used.¹ These bakers can be made by a mechanic at a cost of about \$5.00. For infra red radiation an electric room heater may be used. Radiant heat should be applied to the injured part according to definite directions from the surgeon.² One of the most valuable methods for the application of heat is the whirlpool bath.³ The temperature of the bath is first 100° F. The whirling of water under pressure and the air intake make possible an increase of temperature to 115° F. This is most useful as a preparation for subsequent massage and manipulation of painful stiff joints. Its soothing warmth changes the cold purple of the swollen painful foot, leg or arm into a warm red, thereby softening the parts for massage and exercise and increasing the conductivity of the extremity for electrical treatment. The whirlpool bath is not only a thermal bath but the rapidly moving water and air bubbles give an efficient form of gentle massage. Joint motion that could not be tolerated otherwise may be given while the patient is in the bath.

Massage—Every surgeon should know the elementary principles of massage and should personally administer massage and motion in the early stage of fracture treatment as long as there is danger of displacement of fragments and careful management of the splints is required. In the later stages of treatment he should direct the technician definitely in the type of massage and motion required.

The following are the types of massage useful in traumatic surgery.

1 *Superficial stroking massage* consists of the passage of the hand in one direction over an area of the patient's skin with a slow, gentle and rhythmic movement. This form of massage aims only to produce a reflex effect. The pressure should be firm but gentle and light with the hand adapted to the contour of the patient's body; the muscles of the operator's hand should be relaxed. Rhythmic movements are essential to secure an even stimulus. The direction of the movement is unimportant in this form of massage provided it is always in the same direction.

Superficial stroking massage is that advocated by Mennell for the early treatment of fractures to relieve pain, secure muscular relaxation, overcome swelling and improve the circulation. For instance, on the second or third day after the reduction of a Colles' fracture the dorsal splint is removed and the wrist and forearm are carefully supported on the anterior splint and placed under the electric lamp baker for one-half hour. The surgeon administers superficial stroking massage over the entire dorsal surface of the forearm, wrist and hand. The dorsal splint is then reapplied and the nurse holds the dorsal splint and the arm while the anterior splint is removed and the flexor surface of the forearm, wrist and hand is massaged by the surgeon. The splints are then reapplied. The surgeon directs the technician to give daily massage and exercise to the fingers, thumb, elbow and shoulder. At the end of a week the forearm is removed from the splints for the treatment and relaxed motion is started.

2 *Deep stroking massage* has for its aim the emptying of the veins and lymphatic vessels and the pressing of their contents in physiologic directions. It is important to have the patient's muscles relaxed or the muscle contractions will reduce the lumen of the veins and thwart the main object of this form of massage. The patient should therefore be lying down with the body completely relaxed. This position also favors the influence of gravity on the venous and lymphatic circulation. The movement should be deep and with the muscles relaxed, transmitted to all the structures under the

hand Heavy pressure is not needed as the venous pressure is slight and a heavy and irregular movement may set up a protective reflex muscular contraction which is unfavorable The direction is always with the venous flow The proximal segment should be treated first because if the venous and lymphatic circulation of this area is not improved that of the distal segment will be blocked

3 *Kneading* consists in grasping lifting rolling or pressing a part of a muscle or a muscle group so as to assist venous and lymphatic circulation hasten the removal of waste products from muscles stretch retracted muscles and tendons and aid in stretching adhesions It is used in the late treatment of fractures The operator's hand grasps a part of the muscle (or a group of muscles) lifts it up as far as possible and kneads it Then the same manipulations are repeated a hand's breadth farther up one or both hands being used Where the muscles cannot be lifted as on the back the movements may consist of rolling or pressing one muscle over another

4 *Friction* is a massage movement performed by pressing with one or two fingers or part of the hand closely applied to the skin of the part under treatment and moving it over the underlying parts The effect of friction is to loosen adherent skin or scars free adhesions of the deeper parts such as tendons running over joints and aid in the absorption of local effusions It is commonly used for the smaller parts such as the hand foot and face In the later stages of fracture treatment the patient or some member of the patient's family is instructed in how to give massage treatment at home²

Exercise—Early in the treatment of fracture *muscle setting* is highly beneficial and can be practiced by the patient while his leg is in the splint or cast It consists of the alternate contraction and relaxation of muscle groups without producing motion In a case of fracture of the leg the patient is taught to contract and relax the quadriceps muscle without movement of the knee In cases requiring the arm to be placed in an abduction splint the patient should exercise the deltoid without shoulder movement These exercises should be practiced under the watchful eye of the operator until the

patient has mastered them Their importance should be stressed as they help to maintain muscle tone and prevent atrophy

Active exercise the most efficient factor in the restoration of circulation and muscle strength may be performed by the patient either with or without the personal supervision of the surgeon It may be assistive free or resistive

Assistive exercise is performed with the assistance of another person or of some mechanical means The writer uses most frequently the Genslen sling suspension method The arm or leg which is to be exercised is supported in a sling suspended from above usually a Balkan frame This eliminates the weight of the limb and allows the patient to translate even minimal and scarcely appreciable muscle power into active and readily demonstrable motion

Free exercise follows the assistive type and is that form which is performed by the patient against the least possible resistance The best method of obtaining free motion is by underwater exercise since the buoyancy of water eliminates the gravitational load and exercise can be carried out against the least possible resistance

Resistive exercise is that form of supervised movement which offers resistance to muscle action and is intended to increase the strength of weak muscles by increasing the amount of work to be done In prescribing exercises the writer gives definite directions and has prepared a mimeographed sheet of exercises for each joint³ For many resistive exercises an apparatus is used which can be made by a local carpenter¹

Relaxed movement or passive exercise is carried through by the operator without assistance or resistance by the patient Early relaxed movement is valuable in a case of fracture involving a joint but it requires considerable skill and one must always remember that union must not be jeopardized by too early attempts at motion³

Graduated Muscle Contraction—While the muscles are weak and assistive exercises are necessary painless muscle contraction by electrical muscle stimulation (faradic current) is useful in the restoration of circulation and causes physiologic contractions with all the natural changes dependent on such contractions and with the mechanical

effects due to the direct movement of the joint. The author has designed an apparatus for this purpose that can be made for about \$5.00.¹

When one of the bones of the leg is fractured there is always a long period of inactivity during which the power of muscle coordination is impaired. Since all movement particularly in walking is the result of the contraction of one group of muscles combined with the relaxation of its antagonist muscles, the efficient working of one muscle is dependent on the efficiency in many other muscles. Therefore in a case of fracture of the leg marked weakness of one group of muscles interferes greatly with proper coordination in walking at first. Too often a patient is allowed after weeks of wearing a cast to start weight bearing on his injured leg without previous exercise and even without normal support afforded his foot by a shoe. This patient gets up on crutches, his feet usually in slippers and attempts to walk with his hip rotated externally, his knee stiff and his foot everted thus causing still further muscle strain and loss of coordination.

In the proper treatment of such a case re-education in walking is essential. Again this may be made a simple inexpensive process if the active cooperation of the patient is obtained. The surgeon should supply written directions for re-education exercises in walking to be used in such cases.* The movements should be started before weight bearing is allowed and the surgeon should give instructions as to the number of times each exercise should be performed during a day. All weight bearing exercises should be performed in proper shoes with felt arch supports because the foot muscles become weakened from disuse.

Occupational Therapy—The prescribing of occupational therapy is based on the fact that the best type of remedial exercise is that which requires a series of specific voluntary movements which form an integral part of a more complex series of coordinated movements for the purpose of securing end products and thus furnishing direct incentive for sustained effort. The ordinary physical therapy exercises which are given to a patient last only an hour at the most and the mechanical exercises have certain definite limitations. The human body is more than a machine and the formal repetition of a movement with or without an apparatus is not of maximum therapeutic value as an exercise for there is no psychological stimulant of personal incentive which encourages a sustained effort.

Occupational therapy may be obtained in a curative workshop where there is equipment or it may be applied at home under the direction of the physician and with the help of the family. This latter choice is inexpensive and effective if the patient is willing to cooperate.

For the successful use of physical therapy in fractures it is necessary to have the physician prescribe and supervise the treatment and to enlist the full cooperation of the patient.

XVIII. DISLOCATIONS

GENERAL CONSIDERATIONS

Definitions—A dislocation or luxation is a complete change in the relation of the articular surfaces comprising a joint. Subluxation denotes only a partial change in the relation of the articular surfaces. Total dislocation is the complete separation of a bone from its articulations at both extremities. For instance, the separation of the clavicle from the sternoclavicular and acromioclavicular joints. Traumatic dislocations may be acute, recurrent or habitual or un-reduced. Acute dislocations are caused by direct or indirect forces and rarely by unbalanced muscular action. Dislocations like fractures may be closed or simple, open or compound. The latter are more frequent in the small joints of the fingers and when present in the larger joints they are more serious as excessive direct force is required to produce them.

Diagnosis—The diagnosis is made from the symptoms and physical signs: (1) pain usually severe; (2) loss of function and limitation of motion; (3) alteration of contour as denoted by a change in the relation of bony landmarks; (4) palpation of the extremity of the bone in an abnormal position; (5) absence of the extremity of the bone from the normal position as denoted by a depression or lack of resistance on palpation; and (6) alteration of the length of the extremity. The roentgenograms which should be made in two dimensions or as stereoscopic films confirm the exact relation of the bones. Differentiation may usually be made from a fracture by the physical examination alone. The position and contour are distinctly different in a fracture which can usually be determined at a glance by an experienced eye. Crepitation and a point of exquisite tenderness can be elicited in a fracture and the resistance of the head of the bone can always be palpated. Errors are more frequently made in supracondylar fractures of the elbow, fractures of the neck and greater tuberosity of the humerus and fractures of the neck of the femur. Such

errors are sources of much damage as various structures are injured from repeated attempts to reduce a supposedly dislocated joint when in reality there is a fracture of the bone near the joint. Roentgenograms will of course always differentiate the two conditions.

Complications—Complications are quite frequent and unless recognized at once may cause permanent impairment of function or even loss of a limb. These may be enumerated as follows:

1. **Impairment of circulation**. If the arterial circulation is impaired there will be blanching of the extremity if the venous return is obstructed there will be cyanosis. Unless relief can be secured at once gangrene is imminent especially in arterial obstruction. On examination there may be obliteration of the pulse but this factor alone may often be compensated by collateral circulation. Arterial injury is most often observed in dislocation of the knee with obstruction of the popliteal artery.

2. **Nerve injury** may be due to pressure alone or to traction injury or there may be actual severance. This is more often observed in the brachial plexus in a dislocation of the shoulder, the sciatic nerve in the hip (which may rarely be caught within the joint after reduction) and the musculospiral and ulnar nerves at the elbow. Obviously reduction usually relieves pressure and function gradually returns though traumatic neuritis may persist for several years.

3. **Simple chip fractures** are frequently observed. Gross fractures are of serious consequence.

4. **Interposition of capsule, tendons, fascia or other soft tissues** may prevent reduction by any closed method. The most frequent location is in posterior dislocation of the thumb at the metacarpophalangeal joint with penetration of the head of the metacarpal bone through the capsule (so called button holding) and between the heads of the short flexor tendons. In one instance the author found the aponeurosis of the gluteal

muscles preventing reduction of a perineal dislocation of the hip

5 Injuries to important structures such as the bladder in a dislocation of the symphysis pubis and the spinal cord in dislocations of the spine are well known and require special and immediate attention

6 Traumatic arthritis may follow, with extensive reaction within the joint as indicated by destructive and proliferative changes impairment of a nutrient artery, such as the artery of the ligamentum teres at the hip may cause sequestration and extensive destruction

7 Massive extra articular bone production caused by stripping of the periosteum may impede function or may even extend as a bridge across the joint Myositis ossificans may arise in adjacent muscles for instance in the brachialis anticus after dislocation of the elbow

8 Tenosynovitis and osteoporosis (or bone atrophy) may be serious complications especially in patients over forty years of age This is probably more frequent in a dislocation of the wrist

9 Aseptic necrosis of the femoral and humeral heads Follow up studies of traumatic dislocation of the hip have shown that aseptic necrosis of the head of the femur occurs in approximately 20 per cent of the cases This is due to traumatic injury of the femoral head resulting in disturbance in nutrition and blood supply The changes consist in increasing sclerosis and cystic changes of the femoral head frequently with gradual disintegration of a portion of the femoral head Evidence of aseptic necrosis usually appear within six to eighteen months after injury There is no method of preventing this complication although protective weight bearing for an indefinite period might lessen the possibility This is usually not practical

Treatment—A careful physical examination of the patient is first made including local examination with especial attention to complications A roentgenogram should be made immediately both to give a permanent record of the injury and to enable the physician to treat the injury intelligently Under no circumstances should excessive force be employed as there may be some mechanical obstruction which prevents reduction such

as an interposed ligament tendon nerve or portion of the capsule Deep anesthesia is usually required though with intelligent co-operation of the patient and with adequate analgesia the reduction may frequently be accomplished After reduction the joint should be immobilized in such a position that redislocation is impossible for a period sufficient for complete healing of the injured capsule as a rule this is about three weeks Complications are often prevented by early and gentle manual reduction When there is massive bone production as in ankylosis open operation is indicated but only after there has been complete organization of the new bone which usually requires from six months to one year When there is impairment of the circulation immediate reduction is absolutely necessary or there will be total loss of limb or irreparable damage Exploration is indicated in nerve injury if there are symptoms of severance or after the elapse of six weeks without improvement in function A gross fracture usually requires open reduction

WILLIS C CAMBELL
Revised by J S SIEED

DISLOCATION OF THE TEMPORO-MANDIBULAR JOINT

One or both temporomandibular joints may be involved double dislocation being more frequent The condyle of the mandible is nearly always displaced forward carried under the eminentia articularis into the zygomatic fossa and held there by the contraction of the temporal and masseter muscles The capsular ligament of the joint is torn Posterior dislocation is impossible unless accompanied by fracture of the tympanic plate of the temporal bone

Etiology—Dislocation of the jaw is caused by any force which produces an over opening of the mouth such as a blow on the chin while the mouth is open in the fracture of the mouth open during extraction of a tooth or tonsillectomy or yawning In persons with relaxed muscles and ligaments the dislocation may easily become recurrent

Symptoms—In double dislocation the mouth is held wide open and cannot be closed The chin is protruded Hollow spaces are felt in front of the ears where the con-

dyles ought to be. The patient complains of acute pain. In unilateral dislocation the chin is protruded and deflected away from the dislocated side and a hollow space can be felt in front of the ear on this side.

Treatment—The usual method of reduction is for the surgeon to cover his thumbs with a towel and place them externally to the molar teeth on each side of the lower jaw. Downward pressure is made with the thumbs the chin at the same time being lifted by the fingers placed beneath it and the condyle is thus carried under the eminentia articularis into the glenoid fossa. Proper occlusion of the teeth is evidence that reduction has been accomplished. General anesthesia may be necessary to produce muscular relaxation. After reduction the movements of the jaw should be restricted for a week or ten days by means of a bandage or by fastening the upper and lower teeth together with wires.

ROBERT H. IVY

DISLOCATION OF THE SHOULDER

Dislocation of the shoulder on account of the mechanical construction of that joint occurs frequently and is of great importance for unless after treatment is efficiently carried out recurrent or habitual dislocation is common. Dislocations of the shoulder may be anterior, posterior and superior. Anterior dislocations are far more common and are caused by leverage of the head of the humerus against the inferior margin of the glenoid cavity. In forced abduction the head is forced through the weak portion of the capsule at the anteroinferior aspect between the insertion of the long head of the triceps muscle and the subcapularis muscle. After passing through the capsule the head may lodge just below the glenoid cavity—a subglenoid dislocation below the coracoid process—a subcoracoid dislocation which is far more common or rarely farther inward and below the clavicle—a subclavicular dislocation. The capsule may also tear above this point on the anterior portion of the joint.

There are several methods of reduction of a dislocation of the shoulder. All primary or first dislocations of the shoulder should be reduced under general anesthesia and in some of the habitual dislocations which are difficult to reduce general anesthesia is also

advisable. Attempts to manipulate the shoulder without anesthesia result in unnecessary trauma to the humeral head and soft structures. Perhaps the most satisfactory method of reduction of a dislocation of the shoulder is by direct traction on the arm with the elbow fully extended. The shoulder is gradually abducted to about 60 degrees at the same time outward pressure is exerted against the humeral head in the axilla. In most instances it can be easily replaced in the glenoid fossa by this means. Modification of this method has been described by Milch.¹ With the patient supine the surgeon stands on the side of the dislocation. If the dislocation is a right-sided one the surgeon's hand is placed upon the patient's shoulder so that the fingers grasp the top of the shoulder firmly and the thumb is placed beneath the dislocated humeral head. Thus the right hand fixes the head of the humerus as the left hand gently abducts the arm into the overhead (abducted) position. Meanwhile the head of the humerus is prevented by the thumb from moving downward and as the arm is brought into complete abduction and external rotation the head of the humerus can be gently pushed over the rim of the glenoid and the dislocation reduced.

Posterior and inferior dislocations require somewhat different methods of reduction. A posterior dislocation is usually reduced by traction in the line of the elevated arm while an inferior dislocation is usually reduced by outward traction with pressure on the head of the humerus.

After reduction a roentgenogram should be made to confirm the reduction and to rule out a fracture undiagnosed in the pre-reduction film or produced as a result of the manipulation.

Another method of reduction is the Kocher method the technic of which is as follows:

- 1 The wrist is held by one hand the elbow is flexed at right angles and the shoulder is slowly rotated outward as far as possible.
- 2 In this position the shoulder is flexed by raising the elbow and bringing it across the chest thus approximating the head of the humerus to the rent in the capsule.
- 3 As this movement is made the shoulder is rotated inward and reduction is accomplished usually accompanied by an audible snap.

There is however much difference of opinion

ion as to the rationale of the Kocher method. In many cases this method has proved difficult and somewhat unsatisfactory. It is possible that the theory underlying the Kocher maneuvers is not entirely true also it is well known that occasionally fractures of the head or neck of the humerus may be produced by this method.

Recurrent Dislocation.—There are numerous operative procedures for repair of a recurrent or habitual dislocation of the shoulder. The most commonly used are the tenosuspension method (described by Nicola and Henderson²) and the reconstruction procedure (described by Bankart) which is based upon the premise that recurrence of the dislocation is due to avulsion

been extremely small the results show sufficient range of motion and no pain or other disability associated with this procedure. The Henderson suspension operation has extremely satisfactory results but it requires the sacrifice of the peroneus longus tendon which has some disadvantages.

Neglected Dislocations.—In an old und reduced dislocation of the shoulder there is rapid atrophy of bone and degenerative changes occur in the articular cartilage with in thirty days the formation of scar tissue is excessive. Therefore closed reduction is contraindicated because of the danger of complicating the situation with a fracture. Operation consists of extensive exposure with removal of all scar tissue and reduc-

Fig 41.—Subglenoid dislocation of the shoulder.

of the anterior portion of the capsule of the glenoid labrum from the glenoid. The Bankart procedure which consists in repair of the shoulder capsule has been employed in connection with recurrent dislocation in the present war. Recurrence of dislocation following tenosuspension methods has been reported in a sufficiently high percentage of cases in combat troops to make some other method of treatment seem advisable. So far as requirements of civilian life are concerned the Nicola and Henderson methods have been found highly satisfactory. Our experience with the Nicola operation has been sufficiently satisfactory to warrant continuation of its use as a routine procedure in all recurrent dislocations in civilian life. While our percentage of recurrent dislocations has

tion of the head of the humerus so as to obtain proper articulation with the glenoid. After three weeks gentle active and passive exercises with physical therapy are instituted. Too much force may cause an objectionable reaction. If there is extensive fibrillation of cartilage convalescence may be unduly prolonged with only partially satisfactory results. In other joints such as the elbow arthroplasty is performed at the time of reduction.

Acromioclavicular Dislocation.—Dislocation of the acromioclavicular joint usually manifests itself as an upward displacement of the distal end of the clavicle at the acromioclavicular joint and is of relatively frequent occurrence. If the coracoclavicular ligament is not torn conservative measures

suffice as slight subluxation is consistent with good function of the shoulder. But when this ligament is ruptured as demonstrated by gross displacement permanent disability may result without open operation. Conservative measures are usually not satisfactory. Much more satisfactory results are obtained in cases of acromioclavicular dislocation if a reconstructive surgical procedure is performed immediately after dislocation rather than to wait a month or two with attempts at conservative treatment. Formation of scar tissue will produce arthritic changes in the acromioclavicular joint frequently causing continuation of disability even though the mechanical displacement is corrected. Operative repair of an acromioclavicular dislocation may be of two types: reconstruction of artificial acromioclavicular and coracoclavicular ligaments by the use of fascia lata as described by Watkins¹ and Bunnell² is quite satisfactory; these operations are the procedures of choice in the acute stage of dislocation. In the chronic stage of dislocation excision of the distal $\frac{3}{4}$ inch of the clavicle has recently been advocated by Gurd³ and Mumford⁴ and has given excellent results.

Sternoclavicular Dislocation—Sternoclavicular dislocation is much less common and consists of upward and anterior displacement of the medial extremity of the clavicle. Reduction is easily accomplished by direct pressure on the clavicle but it is impossible to maintain the reduction by any type of external immobilization or fixation. If the dislocation is of sufficient extent to produce disability or deformity surgical repair of the supporting structures of the inner end of the clavicle is necessary. Repair of the capsule of the sternoclavicular joint with wires or fascia across the joint between the clavicle and sternum is usually inadequate and recurrence of dislocation is common following such a reparative procedure. Perhaps the best method of repair of this dislocation is by using a strip of fascia lata passed through or around the end of the clavicle just lateral to the sternoclavicular joint and passing around or under the first rib. The capsule can then be repaired in the usual manner. The results of the operation have been good. Excellent function is possible without reduction.

Dislocation of the Sternum—Dislocation of the sternum is rare the most frequent form being dislocation of the manubrium forward or backward on the gladiolus. Reduction may be accomplished by inserting a corkscrew into the manubrium for traction with a periosteal elevator the fragments are levered into normal relations.

DISLOCATION OF THE SPINE

Dislocations of vertebrae without demonstrable fracture occur for the most part in the cervical spine. Approximately 50 per cent are of the atlas on the axis because of the shallow facets their nearly horizontal surfaces and the normally wide range of motion between them. They are caused by falls diving accidents or such a trivial trauma as unguarded throwing of the head about to look over the shoulder.¹ Non-traumatic dislocations have occurred during the course of an infection of the respiratory tract.² Destructive lesions of Pott's disease and of osteoarthritis may produce secondary luxations.

The usual type of dislocation is unilateral one lateral mass rotating anteriorly until its articular process slips beyond the underlying facet and falls into the intervertebral

notch. Here it is locked against the interior face of the superior articular process of the underlying vertebra (Fig 418 *a*). With incomplete rotary subluxation the articular process catches on the facet of the next lower vertebra before jumping the crest (Fig 418 *b*). With bilateral dislocation if complete the body slides forward and upward on each side until the processes drop into the intervertebral notches. With incomplete dislocation the body slips forward until the articular processes catch on the surfaces of the underlying facets. The subluxation is then maintained by the weight of the head. Posterior dislocation of a cervical vertebra is unusual. It must of necessity be

time and eliminates the useless application of a cast in a case of unreduced dislocation.

Clinical examination reveals malalignment and restricted movements. In bilateral displacements the head is carried forward with the chin at a normal level or acutely flexed on the chest depending on the completeness of the dislocation. In unilateral luxation there is a wryneck with the chin turned away from the side on which the dislocation is located. If the articular process has dropped into the intervertebral notch the head is laterally flexed toward the shoulder of the same side. If the articular process is caught on the crest of the facet the head will be laterally flexed away from the side

Fig 418—Accurately retouched x rays of rotary dislocations of the neck, both of which were successfully reduced later. *a*, Articular process of the fifth vertebra locked in the intervertebral notch of the sixth vertebra. *b*, Articular process of the fifth vertebra caught on the crest of the underlying facet of the sixth vertebra.

accompanied by laceration of the interarticular ligaments or fracture of the pedicles of the vertebra above and the manipulation must be planned accordingly.

Diagnosis—Routine x ray pictures carefully taken and interpreted will show the dislocation in the majority of cases. Additional oblique or posterolateral views may be necessary to show facets and processes. The laminograph^{7, 8} has added much to the accuracy of diagnosis in the difficult region of the upper three cervical vertebrae. In certain milder subluxations or vertebral locks the surgeon must rely on the physical findings and the history despite inconclusive x ray films. Fluoroscopic control during reduction of a severe dislocation gives

of injury. Rotation of the head is possible away from the dislocation but stops short when an effort is made to turn toward the luxation. Discomfort is present but is not necessarily severe.

Transection of the spinal cord or any lesser degree of damage to the cord or spinal nerves may result. Such damages even complete paraplegia may be due to edema or hemorrhage rather than laceration and necessitate prompt reduction. Neurological findings are scant in some cases. However sudden death has followed an inadvertent movement days or weeks later in unreduced cases even when the case had been neurologically symptomless.

Treatment—Closed reduction is the

method of choice. The consensus of modern opinion is that laminectomy is rarely if ever indicated as the treatment for displacement or the accompanying nerve injuries.^{1, 2} At best open operation relieves only the posterior pressure while anterior angling of the cord continues. After reduction if pressure on the cord persists laminectomy should be considered. For closed reduction the operator must have a vivid mental picture of the exact pathologic condition present and the change with each successive step of the manipulation. Reproducing the displacement on an articulated skeleton greatly helps visualization of the problem and its solution. If reduction is not complete a second effort or even repeated manipulations may be required.

Walton's¹¹ method is especially applicable to unilateral dislocations. The operator stands at the head of the table supporting the patient's head and neck as they are drawn beyond the end of the table. One hand is placed alongside the head on the displaced side. The other hand is cupped under the chin from the opposite side. The chin is rotated away from the dislocation unloading it. The heel of the cupped hand is used as a fulcrum while the head is next laterally flexed away from the dislocation until the articular process is lifted above the bony block. With lateral flexion still maintained the head is slowly and firmly rotated back toward the dislocation and beyond normal range until full correction has been secured. Usually a definite click is palpable and audible as the process clears the obstruction. The head is then hyperextended and lateral flexion reversed.

Taylor's¹⁰ technique is safer for a bilateral displacement and in a case in which fracture complications are suspected. The head sling on the patient is attached to a belt about the operator's waist for traction. Counter traction is secured by shoulder straps on the patient held by assistants. Traction is maintained for five or ten minutes until the neck muscles have relaxed and the articular processes have been lifted from the lock. The neck is then hyperextended over the end of the table while the operator uses his hands to maneuver the vertebrae into line. Traction may be continued during the application of the cast if indicated.

After reduction the neck must be kept in hyperextension so that the articular processes will be thoroughly seated in proper position during healing of the damaged joint capsules. Redislocation easily occurs if the patient drops his chin before the repair has been completed or if the ligamentous posterior ligaments have been distracted by prolonged traction.⁴ The most effective immobilization is a plaster of paris corset from the top of the head to the lower rib margin. Skeletal traction by tongs or wire through the outer table of the skull is reserved for cases complicated by fractures of the jaw or extensive head injuries.³ Severe dislocations and those complicated by a lapse of time require the wearing of a plaster corset for at least six weeks. It may then be replaced by a celluloid collar to be worn over a period varying from three months to a year. A collar has the advantage of being removable for physical therapy. In very mild subluxations a Thomas collar worn for three weeks will give adequate protection from unexpected jars and will hold the chin sufficiently high. Should a dislocation recur several times despite complete reduction and prolonged immobilization some form of operative fixation will be required.⁹

In some recent cases reduction may be obtained without anesthesia. In all others general anesthesia results in a better reduction either being used when full relaxation is desired. With the patient under full anesthesia a dislocation of many months standing has been successfully reduced by closed manipulation.¹

Actual dislocations of the thorax and lumbar spine occur as the result of severe fractures. Subluxations or disalignments in the lumbosacral and sacroiliac articulations constitute a large and important field for careful consideration. (See the chapter on Painful Affections of the Lower Back.)

DISLOCATION AT THE ELBOW

Anatomical Considerations—The bony prominences at the elbow are the olecranon the two epicondyles the supracondylar ridges the head of the radius the lower portion of the humerus anteriorly and the coronoid process of the ulna felt in front of the joint (Chene). The olecranon projects posteriorly and is felt plainly except in extreme extension of the arm. The trochlear surface has a downward and inward inclination which makes its outer portion higher than its inner one. The radihumeral joint, on the other hand presents a horizontal line. These two facts tend to explain the greater prevalence of external lateral dislocation over internal lateral ones. From the obliquity of the joint surfaces is produced the "carrying angle." In semiflexion the external condyle is easily seen in acute flexion the radial head hides it. The relation of the bony points is shown in figure 419. In children and in many women and some men, the elbow joint permits the forearm to be extended beyond the straight line of the humerus on account of the relatively small beak of the olecranon. This is one reason why posterior dislocation here is more common in women and children. The elbow is a true hinge joint and owes its strength mainly to its bony conformation.

Types and Frequency—In the order of frequency elbow dislocations follow those of the shoulder and the fingers. They are commonest in males about four to one. In children the condition is much more common than is dislocation of the shoulder. The different forms of dislocation are numerous for the two bones of the forearm may be displaced together in any one of the four principal directions or each may take a different direction or either may be dislocated while the other remains in place. The number of forms is further increased when distinction

is made between complete and incomplete degrees. Owing to limited space, only the more common varieties will be discussed in detail.

Posterior dislocation, the forearm bones being displaced backward at the elbow, is the commonest dislocation in this region (Fig 420).

Etiology—The usual cause is a fall on the outstretched hand with the elbow in extension and the limb in semiabduction. The

Fig 419—Posterior views of the bones of the elbow joint. *A* In right angled flexion. *B* In full normal extension. Note that in extension the tip of the olecranon approaches the internal condyle.

luxation is caused at times when the arm is forced forward and the forearm forced backward as may occur in football and wrestling or when the arm is caught between two objects moving in opposite directions.

Symptoms—There is marked deformity. The olecranon is more prominent posteriorly. The coronoid process and the head of the radius lie posterior to the humeral

*Flason. Fractures of the Humerus Radius and Ulna, D. Appleton-Century Co., Publishers

articulation. The joint is held in rigid semi flexion, the forearm is usually pronated and appears shorter than normal an impression due to the fullness in the antecubital space. The forearm cannot be completely flexed. The normal interrelation of the elbow triangle—the lines between the olecranon and the condyles and between the condyles—is destroyed. In thin persons seen soon after the injury, a decided hollow is noted on each side of the triceps tendon. In addition to a laceration of the ligaments there is laceration of the brachialis anticus muscle which is often stripped up from the anterior surface of the humerus as well as from the coronoid and the shaft of the ulna sometimes with associated fracture of this process

other epicondyle is intact with the humerus and the other moves with the forearm.

Treatment—Reduction is extremely simple in early cases. If the patient is seen within a few seconds or moments after the dislocation simply making traction on the forearm results in reposition. If the patient is a child place him supine on a table flex the arm to the vertical position grasp the lower end of the humerus with interlocked fingers anteriorly and with the thumbs placed against the prominent olecranon push forward letting the forearm fall forward into the flexed position. The more usual method is moderate extension downward and traction on the forearm with counter traction on the arm in a backward direction. This is

Fig. 120.—Posterior dislocation of the radius and ulna. Note also the external lateral displacement, which nearly always exists.

After seven days the dressing is removed and gentle restricted passive motion or preferably active motion through from 15 to 25 degrees is indulged in every second day. At the end of four weeks during which time the elbow has been gradually brought to a right angle all restraint is removed and light stretching and flexion are performed.

The *prognosis* is favorable in children and usually also in adults. Complete extension is the last motion to be perfected; often months will elapse before the joint will extend completely. One must have patience and not force matters.

Fig. 491.—Diagram showing the relation of the bony parts of the elbow in (A) right-angled position; (B) acutely flexed position. Note the relative position of the condyle and the tip of the olecranon in each.

A very distressing and not uncommon complication or sequela is myositis ossificans or ossifying hematoma, which occurs in the antecubital space and frequently causes a much crippled elbow.

Lateral dislocation in the majority of cases is backward as well as lateral. The outward variety is the more common and is usually incomplete and associated with a sprain fracture of the external epicondyle (Fig. 490).

Etiology—Lateral dislocation of both bones of the forearm usually follows a fall on the hand while the arm is extended. It may be due also to forcible abduction or adduction of the forearm.

Symptoms—In complete dislocations the forearm parallels the humerus but being displaced externally the forearm bones are posterior and lateral to the articular surface of the humerus. In external lateral dislocation the internal condyle is prominent and the forearm is usually pronated. In internal lateral displacement the forearm is usually supinated and the external condyle is most prominent. The usual pain, swelling, rigidity and loss of function result. The displacement is usually incomplete.

Treatment—Reduction by direct traction on the forearm with lateral finger and thumb pressure and manipulation is successful. This

dislocation if associated with fracture as is usually the case, easily results in recurrence.

Forward dislocation rarely occurs and is almost invariably associated with fracture of the olecranon or fracture of the humerus which permits the forward displacement. It is almost always due to a fall on the flexed elbow.

Symptoms—The elbow usually swells rapidly and extensively. The humerus can be felt posteriorly except when the olecranon is fractured.

Treatment—Reduction is accomplished by traction on the forearm in the line of its

* *Ellison*. Fractures of the Humerus, Radius and Ulna. D. Appleton-Century Co. Publishers.

deformity together with pressure backward in the antecubital fossa. When the condition is associated with fracture of the olecranon fixation in the extended position is necessary for approximation of the fragments or open reduction for the same reason.

The prognosis of obtaining a well functioning joint should be very guarded for this fracture dislocation occurs in adults.

Divergent Dislocation.—There are two types of divergent dislocation of the bones of the forearm: (a) anteroposterior in which the ulna passes up and behind and the radius in front of the humerus and of which few cases are reported; (b) the transverse type in which the radius passes to the outer and the ulna to the inner side of the humerus. The cause is a fall on the outstretched hand with the elbow in extreme extension. Reduction is accomplished by traction and manipulation in hyperextension replacing the ulna first; the radius is then easily adjusted by finger pressure. The prognosis is guarded depending on the severity of the causative trauma.

Dislocation of the ulna occurs rarely. Cases representing three types have been reported: forward, backward and toward backward. Dislocation is the most frequent and is usually incomplete. A cubitus varus exists. The radius is in place, the olecranon is posterior and prominent and the forearm is in the pronated position. Reduction is accomplished by overextension and traction. Fixation in the acute position is the treatment of choice.

Dislocation of the radius is not an infrequent condition but is usually associated with a fracture of the upper third of the ulna. The dislocation is anterior in the majority of cases but it may be lateral or backward. The injury is usually the result of a fall or heavy blow on the ulnar side of the forearm in pronation.

Symptoms.—The head of the radius is usually felt anterior and somewhat medial to its usual position. There is a depression beneath the lateral radial dimple below the capitellum. If the dislocation is of the posterior type the head is felt posterior and the forearm is deflected to the radial side and pronated. A cubitus valgus is present. In the anterior dislocation the forearm is slightly flexed but this flexion cannot be

augmented beyond a right angle. All motions are painful and limited. In old cases the displacement may be very pronounced.

Treatment.—Reduction is best accomplished with the forearm partially flexed by traction and rotation at the same time making outward and backward pressure against the head. Reposition offers no difficulties in the absence of fractures of the head itself. Maintaining the reduction is difficult at times especially when there is a complicating fracture. Dressing on an internal or preferably a Fulton splint usually suffices. If these measures fail fixation in acute flexion is indicated.

In children the condition not infrequently is unrecognized. In young children from four to six years of age a subluxation or pulled elbow occurs (Malgaigne's subluxation). The usual history is that the child was lifted or jerked by the hand to prevent its falling in going up a stairway or attempting to step up on a curb. The child will not use the arm and it hangs from the shoulder in slight adduction and internal rotation. All motion of the forearm especially supination is resisted. There is tenderness and often a slight depression may be observed over the head of the radius. Reduction is easily obtained by supination and outward pressure on the subluxated head. A sharp click announces the reposition. The child will then use the arm freely. With the possible exception of a sling for a day or so no dressing is necessary. The results are excellent. If the condition is unrecognized the child will frequently have a good elbow but with a very movable radius at the elbow.

Dislocation of the Radius with Ulnar Fracture.—The writers have collected reports of forty-four fractures of the upper third of the ulna. In eight of these the radius was dislocated in seven anteriorly. This combined injury usually results from direct violence such as a blow on the ulnar side of the forearm, a fall or more commonly a blow on the forearm flexed and raised over the head to protect it from injury. It is called a *parry fracture* (Fig. 422). The diagnosis is easily made.

Treatment.—The dislocation should be reduced first by traction, rotation and outward pressure on the head. After reduction of the radius if the fracture of the ulna is

still unreduced, the forearm is flexed and externally rotated. This uses the radius as a lever against the humerus and with traction tends to reduce the ulnar fragments. If this position results in a redislocation, as it often does, a trial may be made with the forearm fixed at a right angle at the elbow. If this fails, it has been found that traction in the extended position on a Thomas arm splint for two weeks frequently maintains the two

or non-union or viscous union of the ulna in a bowed position often occurs.

After-Treatment—In all uncomplicated luxations of the elbow, rest but not absolute fixation should be maintained for from two to three weeks, depending on the age of the patient. Fixation for a period of ten days in the right angled (rarely neutre angled) position is indicated, together with a few degrees of motion after the ten days. After two to three weeks no dressing is used, unless possibly a sling is needed to prevent overextension.

In luxation of the elbow in youth the prognosis is favorable, but it must be guarded in older patients. Loss of motion, especially in flexion, is sometimes encountered. Myositis ossificans and ischemic muscular atrophy are occasional complications. Nerve injuries occur uncommonly.

"Old Dislocations."—In view of the statement made elsewhere that a dislocation of the elbow "grows old" early, frequently in ten days in children and two weeks in adults, it behooves the surgeon to x-ray all injured elbows in order to prevent an oversight, for, as a rule, an old dislocation of the elbow cannot be reduced by closed manipulation after the period mentioned. The pathologic condition is changed by the development of ossifying hematoma and connective tissue deposit filling the joint spaces, plus bone fragments. These prevent reposition. In such cases arthrotomy must be performed as soon as the condition is recognized. In youth the result is usually good, but in adults functional results are much less favorable.

Congenital dislocations, according to Stimson, are rare, and many of the cases reported could well have occurred after birth, even though several were bilateral in character. Those associated with the absence of parts of the ulna or deficiency of the elbow joint might well be congenital. Operative treatment is usually indicated.

Pathologic Dislocations.—A very few "pathologic dislocations" have been reported. The condition is so rare and so easily diagnosed and treatment so unsatisfactory that consideration of the lesion is unnecessary here.

ELDRIDGE L. ELIASON.
JULIAN JOHNSON.

reductions. Some surgeons treat these cases in acute flexion after reduction. If reduction of either is lost, an open operation on the ulna should be performed. The after-care is maintained for two weeks, during which time only slight rotation is performed. The limb is treated as in cases of fracture.

Prognosis.—The prognosis is only guardedly favorable, as subluxation of the radius

*Eliason. *Fractures of the Humerus Radius and Ulna*, D. Appleton-Century Co. Publishers.

DISLOCATIONS OF THE CARPALS, PHALANGES, PELVIS, COCCYX, HIP, KNEE AND ANKLE

Dislocations of the Carpals—There are three common types of dislocations of the carpals all associated with dislocation of the semilunar bone (1) dislocations of the semilunar bone forward (2) dislocations of the semilunar bone forward with fracture of the carpal scaphoid and (3) dislocation of the second row of carpal bones backward upon the semilunar bone (transcarpal dislocations)

lack of motion stiffness much limitation of use of the fingers and considerable pain are noted Sometimes pressure of the semilunar bone on the median nerve results in tingling and numbness over its distribution in the hand

Diagnosis—The following findings establish the diagnosis a swollen wrist twice the anteroposterior thickness a prominence on the front of the wrist a diminution of all motion and pain on effort to move the wrist Roentgenograms in the lateral view show forward displacement of the semilunar bone with the articulating cup pointing forward

Fig 403

Fig 404

Fig 405

Fig 403—Lateral view of an anterior dislocation of the semilunar bone

Fig 404—Method of reducing an anterior dislocation of the semilunar bone by hyperextension

Fig 405—Leather wristlet for support of the wrist during convalescence

Etiology—A great majority of these injuries are the result of a fall on the extended hand. The hand is pushed violently backward and the semilunar bone pops forward. When the hand is then returned to its normal position the semilunar bone remains forward out of place the distal articular surface facing forward or the semilunar remains in the normal position and the os magnum is displaced dorsal to it. Usually there is fracture of the scaphoid.

Symptoms—The patient believes he has only a sprained wrist and may continue to work for hours or even for days. Swelling

(Fig 423). In type 3 the os magnum is dorsal to the semilunar which has remained in normal relation to the lower end of the radius. Roentgenograms made of the normal wrist in two positions are very helpful.

Treatment—Reduction is necessary even if the dislocation has been unrecognized for days. The writer has successfully reduced a fracture that was four weeks old.

Under complete anesthesia with the traction to the hand the wrist is bent backward hyperextended so that the opening through which the semilunar was displaced is reopened and the semilunar bone is then

pushed from the front backward into its normal position between the radius and os magnum (Fig 424) Reduction is a matter

Fig 426—Metacarpophalangeal dislocation of thumb

of pull push and bend. The results of the reduction are then checked by roentgenograms. A compression bandage is applied to

Fig 427—Position for fixation of a dislocation of the metacarpal with a molded plaster splint

allow the swelling or an anteroposterior plaster is molded to the wrist.

Other dislocations of the carpal are treated by similar maneuvers. After ten days

or two weeks of rest, active motion may be begun supplemented by massage. If there are associated fractures, particularly of the scaphoid, longer fixation (ten to twelve weeks) is desirable. A leather wristlet (steel reinforced) holding the wrist in subdorsal flexion may be useful in returning the patient to work (Fig 428). If reduction fails, an open operation may reduce the dislocated bone by leverage. Rarely is removal of the bone necessary. Results obtained at the Massachusetts General Hospital:

1 Dislocation of the semilunar bone forward

Treated by manipulation

Good economic functional and anatomical results

2 Dislocation of the semilunar bone and fracture of the scaphoid

Treated by manipulation

Prolonged fixation (twelve weeks)

Good results

3 Unrecognized dislocation of the semilunar bone and fracture of the scaphoid

Two operations on one man

Bad results. Stiff and painful wrist

Dislocations of the Metacarpophalangeal Joint—Dislocation of the metacarpophalangeal joint of the thumb is the most common dislocation (Fig 426)

Etiology—Forceful hyperextension of the thumb causes the dislocation.

Pathology—Laceration of the joint capsule usually anteriorly occurs. The projecting metacarpal head becomes entangled with the long flexor tendon or between the two heads of the flexor brevis pollicis.

Symptoms—There is deformity of the finger with the proximal phalanx displaced backward and lack of function.

Treatment—The thumb is hyperextended and the base of the phalanx is pulled upward and forward and rocked from side to side to disengage the tendons which are locked about the neck of the metacarpal bone. Traction is of no value as it tightens the grasp of the tendons about the metacarpal head. After reduction a plaster of paris splint is put on the thumb in the flexed position (Fig 427). It should be extended from the wrist to the tip of the thumb nail (position of grasp). Active motion may be begun after one week. If reduction is im-

possible open operation must be carried out. The joint capsule is opened through a posterior incision and the tendons are pushed aside from the neck of the metacarpal bone.

Similar dislocations may occur in the metacarpophalangeal joint of the middle and little fingers. Difficulties may be encountered in a like manner in reduction and here again surgical operation may be necessary. Open reduction should be carried out as soon as the hand can be properly prepared for incision since delay results in a stiff joint.

Results obtained at Massachusetts General Hospital

1 Immediate reduction (closed or open)

Good results

2 Delayed open reduction (closed impossible)

Bad anatomical result poor functional result (stiff joint)

Dislocations of the Phalanges—The various phalanges of the hand may be dislocated in any direction but usually the dislocation is forward or backward. It is often complicated by a small chip fracture. The dislocation is easily reduced under local block anesthesia and the finger held in place by a simple splint or by traction.

Luxation of the distal joint is common. This is usually associated with a drop of the distal phalanx and is called a baseball finger. In baseball finger there is a rupture of the distal portion of the extensor tendon. The finger may be splinted in hyperextension for six weeks. (See section on Rupture of Tendons.)

Dislocations of the phalanges of the foot occur frequently and are usually associated with much swelling of the joint. They are easily reduced and held in place with a simple molded plaster splint or adhesive strip ping.

Pathology—An evulsion of the extensor tendon from the back of the terminal phalanx.

Treatment—An anterior splint is maintained for from four to six weeks. If it is applied immediately it is usually effective. If not the result is a dropped finger and failure of the voluntary extension of the distal phalanx. Late efforts to correct this deformity by splint or surgical operation usually fail.

Dislocations of the Pelvis—These are very rare except when associated with fracture and either follow severe falls or are associated with childbirth. (See section on Fractures of the Pelvis.)

Pathology—The dislocation is caused by the tearing of the ligaments at the symphysis pubis with relaxation of the ligaments of the sacrospinous joint.

Symptoms—Pain is felt on walking on motion of the pelvis and on extreme flexion of the thigh. Separation of the symphysis is palpable.

Diagnosis—A diagnosis is easily made. Roentgenograms show the separation and rising up of one pubic bone from its fellow.

Prognosis depends on the extent of the injury to the contents of the pelvis that is the bladder, ureters and sometimes the rectum. The results in a case of simple dislocation are good.

Treatment—The intra-abdominal injury requires rest in bed and fixation of the pelvis with a pelvic belt until the ligaments are healed. Sometimes traction on the leg with adhesive plaster is necessary to bring the symphysis into alignment. The patient usually can walk after from ten to twelve weeks. In cases of severe dislocation of the pelvis skeletal traction is necessary for reduction.

Intrapelvic Dislocations (See section on Fractures of the Pelvis)—Intrapelvic dislocations of the head of the femur with fracture of the acetabulum follow severe falls directly on the hip. The head of the femur is driven through the acetabulum and impacted in the pelvis.

Pathology—The fractured acetabulum opens and permits the passage of the femoral head into the pelvis.

Symptoms—There is little motion of the hip and relatively little pain. The leg measures about 1½ inches shorter than the other leg. Palpation of the hip shows a depression in the region of the great trochanter.

Treatment—It is often difficult to extract the head from the pelvis but it can usually be accomplished by gentle prolonged manipulation. Traction with the leg in extreme abduction will effect reduction in some cases. Thereafter the leg must be kept in extreme abduction to prevent recurrence of the dislocation until a new acetabular cavity reforms. Usually there is some redislocation.

of the head because the new socket is not strong. However the end result is economically good but only fair functionally and poor anatomically.

Recently there has been some operative work done on the pelvis in an effort to restore the fractured acetabulum—acetabuloplasty but the results have not been satisfactory.

Dislocations of the Coccyx—These injuries are most common in women and may follow passage of the infant's head during childbirth or sometimes follow direct blows over the coccyx. Clinically displacements of the coccyx are anatomical variations or are associated with fracture. A true dislocation is rarely seen.

Pathology—Displacement of the coccyx is usually upward.

Symptoms—A great deal of local pain and discomfort results and unfortunately no method of treatment and no position gives any considerable relief. The patient seems to suffer considerable pain at all times except when standing up or sitting up on a high stool.

Diagnosis—When an examination of the rectum is made with the finger, the dislocation can be palpated. Roentgenographic diagnosis is difficult because of the numerous anatomical variations found.

Treatment—A true dislocation can be reduced by the finger in the rectum. Rarely is surgical intervention necessary.

Dislocations of the Hip—The hip joint is strong and has a wide range of motion. The head projects into a deep acetabulum and is held in place by strong ligaments the strongest being the anterior Y shaped ligament of Bigelow. The muscles about the hip are powerful. The landmarks are the great trochanter, the anterior superior spine, the tuberosity of the ischium and the head of the femur. Dislocation of the hip is usually an injury of a middle aged person and is five times more frequent in males than in females. In children the epiphysis is separated, in elderly persons the neck of the femur is fractured.

Etiology—Dislocations of the hip result from falls or injuries which occur when the thigh is flexed. The injury is uncommon but crippling if not recognized.

Pathology—The head of the femur is

twisted out of the acetabulum and the interior part of the capsule is torn. The head leaves the joint through this tear the Y shaped ligament of Bigelow acting as a fulcrum and comes to rest either in back (posterior dislocation) or in front (anterior) of the joint—rarely above or below (Fig. 428).

POSTERIOR DISLOCATIONS—**Symptoms**—The thigh is adducted and internally rotated, the knee is bent so that the inside of the foot rests on the opposite instep. The great trochanter is pushed upward. The head of the femur can sometimes be palpated in back of the great trochanter and moves with it. There is little motion of the hip. The patient is unable to stand on the

Fig. 428—*a* Posterior dislocation of the hip *b* anterior dislocation of the hip

leg. Roentgenographic examination shows that the head of the femur is out of the acetabulum. There is apparent shortening. The sciatic nerve may be injured when an effort is being made to reduce the dislocation.

Treatment—Allis method. The patient under complete anesthesia lies on the floor. The dislocation is reduced by reversing the path of dislocation using the Y shaped ligament of Bigelow as a fulcrum. The ankle is grasped in one hand, the other hand is clenched, the forearm is placed under the patient's flexed knee and the thigh is flexed (Fig. 429). This brings the head of the femur down. A motion is made as though lifting the patient from the floor. This brings

the head to the edge of the acetabulum. The leg is then rotated inward, lifted again, and

The rotation clears the head of the capsule, muscle, vessels and nerves

Fig 429—Showing the grip used in the reduction of a dislocated hip

Fig 430—Bigelow method of reduction of a posterior dislocation of the hip (Cotton) a The thigh is flexed and gently lifted in abduction with the leg in flexion, b the thigh is rotated inward (foot outward), c the thigh is adducted and rotated upward, d the thigh is abducted, e the thigh is rotated outward (foot inward), f the leg is extended. This is done with a sweeping circular motion without force. In the diagram the heavy arrow indicates the sequence of positions.

then extended. If the head does not pass in the leg is rotated outward and lifted again.

Bigelow method. The thigh is flexed gently lifted in abduction with the leg in

flexion rotated inward (foot outward) adducted rotated upward abducted rotated outward (foot inward) and extended This is done with a sweeping circular motion with out force (Fig 430)

ANTERIOR DISLOCATIONS—Symptoms—Anterior dislocations are very uncommon resulting from injuries which cause extreme abduction of the leg The head twists out of the acetabulum tears the lower part of the capsule and rotates forward The Y shaped ligament is uninjured The thigh is abducted and rotated outward in extension The head of the femur may be palpated in the groin below Poupert's ligament

Treatment—Alis method The thigh is flexed and abducted An assistant places one

Fig 431—Application of a con press on fan lace to the knee by the Alis method. Layers of absorbent cotton wool is secured tightly with an elastic bandage

hand in the groin and pushes the head outward and backward while the surgeon lifts and adducts and finally extends the leg

Bigelow method The thigh is lifted flexed abducted rotated inward (foot outward) and extended

Prognosis—After reduction the patient should be kept in bed for two weeks usually with the feet tied together There is no reason why weight bearing should not be begun after three weeks and continued with care As the rent is at the bottom of the capsule there is no reason for recurrence in ordinary use of the hip

Dislocations of the knee—Dislocation of the knee occurs very rarely The writer has seen only three cases The dislocation

may be anterior or posterior

Etiology—A fall on the flexed knee causes the dislocation

Diagnosis—The deformity is obvious In anterior dislocations the crest of the tibia is higher than the thigh in posterior dislocations it is lower

Treatment—The dislocation is reduced by gentle traction on the lower leg The bones usually slip into place Sometimes more manipulation is necessary The muscle power of the thigh must be maintained through exercises

After Treatment—A plaster of paris splint should be worn for six to eight weeks and protection continued for some weeks thereafter There has been considerable tearing of the capsule and one must expect some limitation of motion

Dislocations of the Patella—Etiology—These dislocations are more common in women They are associated with knock knees and may be caused by direct injury to the patella or severe blows often being the result of a fall with the knees flexed and adducted The displacement is always outward

Pathology—The ligaments and tendons about the patella are torn

Symptoms—The knee is flexed with pain and swelling The intercondylar fossa is empty There is usually hemorrhage into the joint and the patella can be palpated outside the condyle

Treatment—Under anesthesia the knee is flexed and the leg extended Compression dressings will reduce the hemorrhage into the joint Atrophy of the muscles of the thigh may be minimized by exercises before and after operation

Prognosis—So much injury has been sustained by the ligaments that recurrent dislocations are frequently reported especially in childhood because of knock knees and other anatomical conditions Surgical intervention may be required to direct the power of the quadriceps muscle toward the weight bearing line and to repair old tears in the capsule

Dislocations of the Ankle (See section on Fractures about the Ankle Joint)—Practically all fractures of the ankle have associated with them some degree of dislocation The reduction of the fracture carries with

DISLOCATIONS OF THE ASTRAGALUS

it the reduction of the dislocation. Uncomplicated dislocations of the ankle are rare and occur only forward or backward because of the depth of the ankle mortice. In *posterior dislocations* the lateral ligaments are lacerated, and the astragalus is forced backward beyond the tibia. *Anterior dislocations* are very rare.

Diagnosis—The position of the foot readily indicates the diagnosis, which can be confirmed by means of roentgenograms.

Treatment.—In cases of posterior dislocation

inner side of both heels (Thomas heel inside being raised $\frac{3}{8}$ inch and built for $\frac{1}{4}$ inch).

Dislocations of the Astragalus.—*ogy*.—These dislocations result from or a twisting of the foot, usually associated with considerable violence. The astragalus is partially or incompletely torn out of position. A *subastragalar* dislocation is rare but must be kept in mind for occurs, it must be promptly reduced (open reduction (prompt) is necessary

Fig. 432.—Fracture-dislocations of the ankle. *a*, inward; *b*, outward; *c*, posterior; *d*, anterior; *e*, upward.

tion the lower part of the leg is pushed backward and the heel forward. In cases of anterior dislocation this motion is reversed; the lower part of the leg is pushed forward and the heel backward. Usually no difficulty is experienced in effecting a reduction.

Prognosis.—The foot should be kept in dorsiflexion at right angles to the leg from four to six weeks. Early active motion with the cast in place is recommended. During convalescence the foot should be strapped in inversion. It is also well to build up the

Diagnosis.—The articular surface of the astragalus is palpable inside and in front of the ankle. There is much tension of the ligaments. Roentgenograms are difficult to interpret because of the distortion of the bones. The dislocation is often compound, and the blood supply of the bones is damaged.

Treatment.—An attempt should be made to effect reduction by manipulation, spreading the joint on the side of the tibia and pushing the astragalus back into place. If closed reduction is impossible, open

ation is necessary. Excision of the bone gives poor results. Fusion of two adjacent bones is more satisfactory.

In cases of compound fracture the joint should be cleaned and the bone replaced. This however is a dangerous procedure and in many cases amputation of the foot is necessary. A compression bandage and plaster splint are applied and the protection of a splint is needed for from six to twelve weeks.

Dislocations of the Tarsometatarsal Joints—One or more metatarsals may be dislocated laterally on the tarsal bones.

Diagnosis—Roentgenographic examination is necessary to demonstrate the lateral displacement.

Treatment—If treated early a dislocation is easy to reduce but difficult to fix because of the flatness of the joints. Fixation in a molded plaster of paris splint is sometimes successful but it is usually necessary to operate and hold the dislocated bone in place with sutures or screws.

After Treatment—The foot must be supported for two or three months.

The end results are usually poor.

HENRY C. MANBLE

XIX. THE HEAD

THE SCALP

Anatomy—The scalp is composed of five layers. Immediately beneath the skin is a layer of subcutaneous fatty tissue made up of small lobules of fat enclosed by many dense fibrous bands uniting the skin closely to the galea aponeurotica. Between the latter and the pericranium is rather loose subaponeurotic connective tissue. Movement of the scalp on the skull is in this loose tissue. As the subcutaneous tissue is very dense, effusions collect in the loose subaponeurotic layer and its close connection with the galea decreases its usual redness and swelling in skin infections. The skin contains many sebaceous glands and it is obstruction of these glands which causes the retention cysts (wens) commonly seen on the scalp. Larger blood vessels and lymphatics are found in the loose subaponeurotic tissue communicating by way of the emissary veins with the intracranial venous sinuses and are thereby a source of dangerous extension of infections. The blood supply through the paired occipital, postauricular, temporal and supraorbital vessels is abundant and widely anastomotic. The pericranium is slightly adherent to the skull except at the sutures where the attachment is firm.

Cephalhematoma is the collection of blood between bone and pericranium more frequently seen as an accident of birth or a result of birth injury. It is thought to be related to possible injury of the outer table of the incompletely ossified skull. One or two days after birth there is seen a swelling limited in area to one bone usually the parietal. It is fluctuant and the surrounding skin is dark. The borders may feel slightly thickened owing to the presence of blood clot. Later the pericranium proliferates and if the blood is not soon absorbed may begin to produce bony callus and ultimately a thin layer of bone diffusely over the swelling. From the diagnostic viewpoint it is to be differentiated from caput succedaneum, a circular circumscribed edema of the scalp brought about by prolonged pressure in the birth canal. The latter is not limited by the cranial sutures, it contains a bloody serum, pits on pressure and does not fluctuate. Cephalhematoma usually disappears spontaneously within two or three weeks after birth. If this should not be the case aspiration is generally useless as any ordinary aspirating needle is too likely to be obstructed

by blood clots. It is then necessary to evacuate the mass through a small incision followed by pressure over the entire area. A sterile sea sponge kept in bichlorid of mercury solution and then wrung dry is invaluable in the application of a firm pressure over the evacuated area.

Scalp Wounds—Occasionally a localized blow on the adult scalp is severe enough to bring about rupture of blood vessels and resulting hematoma without actually causing an open wound. When this happens the entire extravasation of blood takes place in the loose subaponeurotic space. It is to be differentiated from a depressed fracture which it sometimes simulates because a firm area at the periphery made up of blood clot may be mistaken for the edge of bone. When there is actually serious doubt whether or not the condition is a depressed fracture an x-ray should be taken or an exploratory incision made. After evacuation pressure is applied. The presence of any skin abrasion should be a danger signal for possible infection which may enter and extend beneath the galea.

An open wound of the scalp may be produced by any localized sharp or blunt force. The scalp is relatively inelastic and the force of a blow expended on the skull causes a rupture of the skin and galea and frequently of the pericranium. Such injuries entail definite risk of infection with widespread extension beneath the galea. The scalp has a rich blood supply, and hence healing is sometimes surprisingly good even when a considerable area is involved.

Treatment—Treatment is determined by four factors: the character of the wound, the condition of the tissues, the amount of soiling and the time which elapses between the injury and surgical care. A cleanly incised wound without tissue destruction seen within six hours of the injury should be sutured. A grossly dirty contused wound if seen more than six hours after injury should not be treated by primary suture. Between these examples of mild contamination and

frank infection are occasions which call for individual surgical judgment. Panshaking cleaning combined with modified wound excision will frequently permit primary suture of wounds which otherwise should not be closed. Dry sterile gauze is first placed in the wound and the involved parts are shaved after softening with green soap. Local anesthesia is preferable in all cases when reasonable cooperation of the patient may be expected. The surrounding skin is then scrubbed thoroughly with soap and water. Hydrogen peroxide is useful for removing dried blood but should be kept out of the wound. Ether is useful to remove grease and may be used in the wound without ill effect. One of the tinted antiseptics is then used on the skin up to the wound edge. Following this preparation and after removal of the gauze the wound is irrigated with liberal amounts of saline solution and examined thoroughly both for the presence of foreign bodies and the possibility of bone injury. Ostensibly crushed and devitalized tissue should be removed (debridement). Complete wound excision is not usually practicable in the scalp. Bleeding usually can be controlled by pressure on visible sources but when it is persistent sutures properly placed are preferable to ligatures. Interrupted sutures of silk or cotton are used both in skin and in galea. Bare bone should always be covered. When loss of tissue necessitates shifting of adjacent scalp the separation is made through the galea and the secondary defect covered immediately by a split skin graft or after several days. Extensive laceration of the scalp may be so severe as to be almost an avulsion. However extensive there is sometimes left a large pedicle with sufficient blood supply so that suture in position is followed by healing.

Avulsion of the Scalp.—The commonest cause of complete avulsion is an industrial accident usually to a woman. The separation takes place between galea and pericranium which is usually left attached. If untreated the latter soon disappears exposing the cranial bones. The blood supply following this accident is usually inadequate so that the cranial bones soon assume the dry yellowish appearance typical of slow necrosis, the degenerating bone being cast off very slowly.

Treatment.—After the patient's recovery from shock all parts of the scalp which are not obviously devitalized should be replaced and bleeding controlled by ligature and suture. Denuded bone should be covered by the flaps and exposed pericranium should be split skin grafted either immediately or within a few days. If these grafts fail it is advisable very early to make multiple perforations of the outer table of the skull thus stimulating the diploe to form granulation tissue. This will in time cover the entire denuded area and offer a sound base for skin grafting. These perforations should be about 1 cm apart and should penetrate the outer table until definite bleeding occurs.

Tetanus antitoxin should usually be administered and gas bacillus antitoxin will be definitely indicated in many cases of extensively contused wounds. Sulfanilamide powder sprinkled in these contaminated wounds has many advocates. Since the sulfonamides are inhibited by procaine (novocain) which is a para aminobenzoic acid derivative, nupercaine is preferable for local anesthesia when local sulfonamide is used. If effective sulfonamide medication is desirable oral sulfadiazine best answers the purpose. Penicillin will be useful.

Wounds which are suspected of being infected should be examined daily for at least four days. The presence of infection may not manifest itself by redness of the skin but rather by a shiny boggy and tender swelling which may extend for some distance away from the incised area. Infections of this sort should be treated according to the methods outlined under infections of the scalp.

Infections of the Scalp.—Apart from wound infections the common infections of the scalp are furuncles and carbuncles and the infections secondary to the presence of pediculosis, ringworm and impetigo. Dry scabies and cellulitis may follow trivial wounds or abrasions. Both furuncles and carbuncles are more common posteriorly on the part of the scalp near the neck. The thick skin predisposes to downward extension rather than spontaneous discharges of pus. This downward extension may extend through blood vessels and through the subcutaneous tissues to the intracranial sinuses. When infection has penetrated beneath the galea its spread is rapid and eradication dif-

sult. Considerable pain and neighboring edema develop accompanied by fever, leukocytosis and regional lymphadenitis. If wound infection is limited removal of one or two stitches and the use of warm compresses will often be sufficient. If the infection has definitely extended beneath the galea it is necessary to insure drainage of this area. Small incisions should be placed in dependent portions of the swollen area and small rubber drains in the subperiosteal space. When the pericranium has been incised the infection may spread beneath it. In such a case it is limited in its spread by the strong attachments of the pericranium to the cranial sutures.

Osteomyelitis of the cranial bones may follow infections and separation of the periosteum. The latter soon perforates and pus accumulates in the subperiosteal layer. This is frequently referred to as Pott's puffy tumor and may also be accompanied by a collection of pus between the bone and the dura.

The treatment of any infection of the scalp is based on careful recognition of the layers involved. Adequate drainage is necessary especially in dependent portions. Sometimes these incisions must be so extensive as to seem unnecessarily radical but the unsatisfactory results following conservative treatment speak for themselves.

Burns of the Scalp—These are better treated by other methods than tannic acid coagulation. When the patient is first seen it may be difficult to estimate the depth of the injury and it is important that all structures not destroyed by the burn be preserved. Hair follicles, galea and even pericranium that have not been burned may be destroyed by tanning. These burns should be treated with sterile petrolatum or boric acid ointment applied on fine-meshed gauze reinforced by moderate pressure. Many burns treated in this manner will not need grafting as epithelialization will proceed from the corium and the bases of undestroyed follicles. However, once it becomes apparent that such epithelialization is not proceeding skin grafting should not be delayed. If a granulating surface is allowed to heal by peripheral epithelial growth an unstable scar results. If pericranium has been destroyed exposing the outer table of the

skull treatment depends on the viability of the latter. Early multiple perforations will allow the diploe to granulate but it may sometimes be time saving to remove areas of the outer table. A split skin graft is best in this location.

Tumors of the Scalp—The common tumors of the scalp are basal and squamous cell epitheliomas. They may originate in unstable scars from the lining of sebaceous cysts from senile keratoses or from apparently normal skin. These tumors should be excised with a good margin particularly on the lymphatic drainage side. Closure of the defect offers no problem as the elevation of the scalp allows it to tolerate marked insult. Relaxation incisions sliding or rotating flaps and split skin grafting are useful here. When the skull is involved either by the tumor itself or by irradiation osteonecrosis it must be removed. The dura thus exposed must be covered immediately as its ability to produce granulation tissue suitable for grafting is almost negligible. For small defects single-pedicle flaps may serve but for larger ones a double pedicle flap made up of an entire segment of scalp must be used and the donor area covered with a split graft.

EDWARD M. HANNAHAN

INJURIES AND SURGICAL INFECTIONS OF THE EYES AND ADNEXA

The most frequent injury of the eye is caused by the deposit of a foreign body on the cornea. Care in removing a foreign body completely under aseptic precautions is most important because if it is neglected or improperly removed a severe purulent keratitis (serpiginous ulcer) may result often leading to loss of the eye. When seen late if the slightest gray or yellowish infiltrate is present this must be sterilized by the careful application of pure trichloroacetic acid or tincture of iodine and the eye watched carefully.

Intraocular foreign body is to be suspected after any injury to the eye even a seemingly trivial one. In such cases roentgenograms should be made by a method which will localize the foreign body with relation to the globe. The Sweet method is usually employed but if proper instruments and tech-

nic are not available the insertion of small pieces of silver wire under the conjunctiva above and below the cornea will usually provide the necessary information when they are seen in frontal and lateral views. They are inserted under local anesthesia through minute conjunctival incisions and are removed after the roentgenograms have been taken.

If the foreign body is located in the orbit but outside the globe it may usually be left unless it interferes with the movements of the globe or infection develops. If it is located inside the globe and is of some magnetic material it should be removed at once with a magnet. One of the giant models is usually necessary though larger particles may sometimes be removed with a small hand magnet. If the nature of the foreign body is unknown a trial with the magnet will determine whether or not it is magnetic. This should not be undertaken however unless the body has been properly localized. As much care must be taken in such a trial as in removing the foreign body. Opinions differ as to the best route for removal of a foreign body in the posterior segment. A skilful operator is usually successful in drawing the fragment around the lens into the anterior chamber whence it is removed through the original wound or through a small section at the limbus. Others will prefer to remove it directly through a scleral incision near its site.

Non magnetic foreign bodies can seldom be removed unless they are in the lens or anterior chamber. An eye which is harboring a foreign body is a possible source of sympathetic ophthalmia but may remain quiet with more or less useful vision for many years. Hence it is usually best to watch such an eye closely for signs of iridocyclitis and if the signs occur and do not respond rapidly to treatment the eye should be removed. Injections of foreign protein large doses of sodium salicylate or sulfanilamide and the local use of atropine comprise the usual treatment in a case of intraocular foreign body.

Lacerations of the lids may usually be repaired at once unless seen after infection has developed. The wound is first washed with sterile saline solution and touched with half strength tincture of iodine. The con-

junctival sac may be washed out freely with 1:2500 metaphen or a similar antiseptic. Careful apposition of the edges at the outset will save much work later in correcting cicatricial deformities. Because of the excellent vascular supply the introduction of drains is seldom necessary. An exact knowledge of the anatomy and function of the parts is necessary for proper closure of an extensive wound of the lid. When a wound involves the entire thickness of the lid it is important to close the conjunctival wound separately as otherwise bands of scar tissue will develop and interfere with the movements of the globe or with the wearing of a prosthesis. Even though it may be difficult to open the lids the exact condition of the globe must be ascertained. In the case of a dirty wound of the lid or globe a prophylactic injection of 1000 units of tetanus antitoxin should be given at once.

In the case of a perforating wound of the globe one must decide whether or not the eyeball may be preserved. If no vision is present or only perception of light with faulty light projection it is usually best to sacrifice the eye or its contents as the prospect of regaining useful vision is nil and retention of such an eye may involve the danger of sympathetic ophthalmia. When useful vision or even correct projection of light is present an attempt is usually made to save the eye. A small wound in the corner without prolapse of the iris will often heal smoothly if both eyes are immobilized under a dressing which should include a rigid shield to prevent further trauma to the globe.

If the wound is large and includes a prolapse of uveal tissue it must be closed by covering it with a sliding conjunctival flap. Direct closure by sutures through the cornea or sclera involves too much traumatism to the eye with possible loss of vitreous or damage to the lens. Careful local anesthesia and injection of 4 per cent novocain at the outer orbital margin to paralyze the orbicularis muscle are essential preliminaries. The conjunctiva is gently dissected away from the wound and undermined so that it may be pulled over it with the slightest traction. Two or more stitches are inserted in such a position as to pull the conjunctiva well over the wound when tied and one turn of each knot is placed while

the stitches are left loose. The wound is touched carefully with pure liquefied trichloroacetic acid and if the cornea is involved it is also applied carefully to the under surface of the flap so that it will adhere to the cornea. Then and not until then the prolapsed uveal tissue is cut off with one snip of sharp iris scissors and the stitches are tied. Previous excision of the prolapse would allow the escape of vitreous or the lens during subsequent maneuvers. Atropine is instilled a dressing with a rigid shield is applied and the patient is put at rest. As a prophylactic against infection an injection of foreign protein is usually administered and in the case of a dirty wound this may well be tetanus antitoxin. Sodium salicylate is administered after twenty-four hours.

The watch for complications then begins the commonest of these being intracocular infection. If many pyogenic organisms have been introduced a purulent infection will rapidly manifest itself and will usually require excision of the ocular contents. Milder forms of infection often occur which may subside under treatment with foreign protein and the salicylates or sulfanilamide. If the reaction following an injury is not subsiding after two weeks of treatment the eye must often be sacrificed in order to prevent sympathetic ophthalmia.

Enucleation of the globe is the operation usually performed. The conjunctiva is dissected from the limbus and is then undermined all around and far back on the globe. The four rectus muscles are caught on a hook and cut off at their insertions.

Strong curved enucleation scissors are inserted beneath the conjunctiva at the nasal side until the optic nerve is felt. This is cut quickly while the globe is pulled forward by fixation forceps attached to the stump of the external rectus. The remaining attachments are then cut including the attachment of the two oblique muscles. A purse-string suture may be used to close the conjunctiva though this is not necessary. This operation if performed without injury to the conjunctiva allows the wearing of a prosthesis. The stump left is small however and usually a glass or gold ball is inserted in Tenon's capsule and the muscles and capsule are carefully sutured over it.

An operation which leaves a stump at least as good as that obtained by an implant in Tenon's capsule is simple *exsiccation* of the ocular contents. An incision is made from the outer ciliary region bisecting the corner and anterior segment to the inner ciliary region. An excision spoon is inserted and the entire uveal tract retina and lens are removed at one scooping movement. The inside of the sclera is wiped carefully with large sponges so that no shreds of uveal tissue remain. The corneal incision is not sutured but is held together by a large glass ball (2 cm in diameter) or by a sponge placed beneath the lids and held in place by a dressing for forty-eight hours. This operation is suitable in an early wound and if a purulent infection of the globe is already present. When sympathetic ophthalmia has developed or its presence is suspected enucleation is the surgical procedure to be preferred.

Traumatic cataract is a common complication of penetrating wounds and may occur even after blunt contusion by rupture of the lens capsule. If the lens swells rapidly causing pain and increased intraocular tension it must be removed at once. More commonly swelling is slight but the whole lens becomes opaque within a variable period. In such cases removal is deferred until all signs of reaction have subsided—usually after several months. In some cases a localized opacity of the lens occurs which remains stationary with little or no disturbance of vision and removal of the lens is not required. In persons under the age of thirty, the lens material is soft and may be removed by gentle pressure through a small corneal incision. In older persons a hard nucleus is present and a larger limbal incision with a conjunctival flap is required. A patient who has had one lens removed the other eye being normal will usually prefer not to wear the strong convex glass which is required for good vision. However this should not deter the surgeon from advising removal of the traumatic cataract when the opacity is complete as useful vision is present without correction and the eye is placed in the best condition against the time when it may be needed.

CANCER OF THE LIP

Definition—The term cancer of the lip is usually limited to those growths arising on the vermilion border or on the mucocutaneous junction of the lips. Lesions arising on the skin separate from the vermilion border should be classified with other carcinomas of the skin of the face.

Etiology—Cancer of the lip comprises about 30 per cent of all malignant tumors of the oral cavity. While the most frequent it is the least malignant form of intraoral cancer. The average age of occurrence is 56 years although in about 10 per cent of cases the growth develops before the age of 40. It is rare in women over 90 per cent of the cases occurring in men. In about 90 per cent of all cases the growth arises on the lower lip where the effects of chronic irritation from exposure to sunburn, dryness, chapping, biting or smoking are most likely to occur. The upper lip is relatively well protected from these etiologic factors and is rarely (5 per cent) affected by primary cancer. Syphilis is not as great an etiologic factor in cancer of the lip as in other anatomic forms of intraoral cancer.

Pathology—Cancer of the lip is preponderantly squamous carcinoma grade 2. Papilloma or squamous carcinoma grade 1 may occur. Growths of the lip developing in scar tissue following thermal or radiation burns are likely to be spindle cell carcinoma.² Sarcoma of the lip is extremely rare.

Symptoms and Clinical Course—Cancer of the lip usually appears as a small plaque or ulcer which is indurated well beyond the borders of any visible disease. Pain and tenderness are characteristically absent. The patient is likely to attribute the lesion to a simple cold sore and fails to seek medical advice until the growth is about 1 cm in diameter. In later stages widespread invasion, ulceration and erosion of the lip occur with metastases to the cervical nodes.

Metastases tend to appear relatively late but are present in about 25 per cent of cases when the patient is first seen by the physician. The nodes most frequently involved are the submaxillary, next the submental and finally the upper deep cervical. If the lesion is well to one side of the midline the nodes usually appear on the same side.

Diagnosis—An early lesion may be confused with herpes kerato es, benign fissure, leukoplakia or tubercular or syphilitic ulcer. There should however be little difficulty in making a diagnosis. Any indurated ulcer of the lip which persists for more than a month is probably cancer. A syphilitic lesion resembling cancer will disappear after less than three weeks of aggressive antisyphilitic treatment. A tuberculous ulcer presents a pale yellow base without ulceration; it is usually tender and painful and a differential diagnosis can as a rule be made quite easily.

When any doubt exists a biopsy is essential. The specimen should be taken from the indurated edge of the ulcer either with a biting forceps or with a scalpel. Unless the surgeon assumes all responsibility for error a biopsy should be made before either irradiation or surgical treatment is undertaken.

Treatment—The treatment of cancer of the lip should be based mainly on a consideration of the pathologic anatomy and on the characteristic clinical course. The primary lesion arises in an anatomic structure which is readily accessible to either radiation or surgical treatment and which may be partly or wholly removed and the defect repaired without serious surgical shock or interference with any vital function. As compared with the other malignant growths of the oral cavity, cancer of the lip is the least malignant and the clinical course is less rapid so that the primary lesion may be treated first. After healing has taken place any cervical metastases may be treated separately. The treatment of the primary lesion and that of the cervical metastases are best considered and undertaken as separate problems except occasionally in the advanced stages of the disease.

For a growth of the lower lip up to 1.5 cm in diameter a permanent cure will result if the primary lesion alone is completely eradicated by any method (operation, radium or x rays) since at this stage of the disease metastases have occurred in only about 10 per cent of cases. This has an important bearing on the management of supposed but nonpalpable cervical metastases—a problem which will be considered presently.

Treatment of the small or moderate-sized lesion is equally successful by either surgical

excision or radiation if properly applied. The V-shaped excision produces moderate deformity, the degree varying directly with the amount of tissue excised. A safe excision is always a wide one and must extend at least

7 to 10 mm from any visible or palpable evidence of the tumor. Since the surgeon is usually influenced by the desire to avoid a great degree of cosmetic defect, he frequently

Fig. 433—Cancer of the lip treated with low voltage x-rays

Such radiation may be in the form of radium or x-rays. Radium or radon is usually applied in contact with or at short distances from the lesion.

allows too narrow a margin and recurrences are not uncommon. The V-shaped excision is not a difficult operation and may be done with the use of infiltration or conduction anesthesia.

Fig. 434—Advanced cancer of the lip treated by wide surgical excision and closure

Irradiation of a small or moderate sized lesion has many advantages over surgical ex-

cision. Radium or radon needles or seeds inserted into the growth are sometimes advocated but when used alone are likely to result in undue scarring or delayed healing. Low voltage highly filtered x-radiation applied to the lesion after careful protective shielding of the adjacent normal tissues is one of the

most satisfactory methods (Fig 433) A moderately advanced lesion sometimes requires a combination of external radiation (x rays or radium) and small doses of radon seeds implanted into the deepest infiltrating

not easily controlled by radiation except with intense doses which are often followed by delayed or imperfect healing with a resultant defect (Fig 434) In such cases it is impossible to obtain a good cosmetic re

Fig 435.—These basic methods alone or in combination with slight modifications may be successfully used for the repair of almost any defect which is likely to result from excision of extensive cancer of the lip

base of the lesion. A discussion of the details of the technique and dosage is beyond the scope of this chapter.

Advanced bulky infected cancer of the lip which has invaded or eroded deeply is

sult and all efforts should be directed toward the saving of life with an acceptable functional result. Such a purpose is accomplished most expeditiously by wide surgical excision and plastic closure (Fig 435) provided any

cervical metastases if present also permit of a reasonable chance of control. A wide extent of the disease in the lip or even invasion of the mandible does not always preclude complete eradication and acceptable functional closure of the defect by aggressive surgical treatment.

In such extensive cheiloplasties excision of the lip and excision of palpably involved cervical nodes are usually performed at the same time. It is unwise to attempt radical or complete neck dissection in connection with such an operation. It is of great advantage if the surgeon is also a competent radiologist and has radon seeds available for the implantation in any unremovable portions of the growth. He should employ radiation for widely separated single nodes after an extensive operation rather than attempt to control by more extensive dissection of the neck.

Treatment of cervical metastases in cancer of the lip is a serious problem. Provided the primary lesion is under control the nodes are operable and the general condition of the patient will permit of a major surgical procedure neck dissection is often a useful and effective measure in a case of cancer of the lip for palpably involved cervical nodes. The procedure should preferably be performed with the use of local anesthesia and since the metastases from cancer of the lips in the operable stage seldom extend beyond the submaxillary and upper deep cervical region the dissection need not extend below the level of the omohyoid muscle in most cases. The submental region should always be included.

For metastatic nodes which are inoperable because of deep fixation or because of the general condition of the patient a combination of external and interstitial radiation is often successful. Such treatment is applied only locally to the single node and may be repeated if and when further nodes appear.

It has been found on analyses of large series of cases of cancer of the lip that when these patients present themselves without palpably involved cervical nodes permanent cure will follow adequate treatment of the primary lesion alone in 90 per cent of cases that is to say in only 10 per cent of this group will metastatic cervical nodes develop subsequently. Despite this significant fact

some surgeons advise prophylactic neck dissection in the absence of palpably involved nodes. The illogic of prophylactic neck dissection in cancer of the lip is apparent when one considers that the procedure can be of possible value in only 1 of 10 cases while carrying with it a mortality of 5 to 10 per cent.³

Prophylactic radiation in the form of one or two skin erythema doses to each side of the neck also seems illogical since this dosage does not produce any noticeable effect on cancer of the lip when actually present. Radiation in lethal doses for cancer (six to eight skin erythema doses) to the entire potential metastatic region in the neck is beyond the point of average tolerance and for that reason it seems most reasonable to give no treatment whatever to the neck in cases of cancer of the lip unless there is palpable evidence of metastases.

Prognosis and End Results.—Cancer of the lower lip is the least malignant form of intraoral cancer. In early cases in which the lesion is 1.5 cm. or less in diameter a cure should be obtained in practically 100 per cent of cases if the patient is regularly observed and examined for recurrence. Failures often result from inattention to proper follow up either by the patient or by the physician. Cancer of the upper lip is a more malignant form of the disease and has a worse prognosis than that of the lower lip.

Various percentages of cure are reported in the literature, the higher figures invariably being based on selected early cases or cases in which the growth was operable. A recent survey at the Memorial Hospital, New York,⁴ which included all patients admitted (early, recurrent and hopelessly advanced cases) gave a net five year rate of cure for 70 per cent when surgical treatment or radiation or a combination of the two was given as indicated in the individual case.

CANCER OF THE TONGUE

Definition—The term cancer of the tongue should include all malignant growths arising on the surface or in the body of that organ. The surface limits are posteriorly the valleculae and anteriorly and laterally the junction of the tongue with (but not including) the floor of the mouth. Growths originating in the mucosa of the floor of the mouth anteriorly or laterally possess clinical and anatomic characteristics deserving of a separate classification. The disease is almost invariably of epithelial origin and therefore arises on the surface.

Etiology—Cancer of the tongue is one of the most common anatomic forms of malignant growth of the oral cavity and comprises about 20 per cent of all intraoral tumors. It is mainly a disease of middle or old age but 25 per cent of the patients are less than forty years old. As in all forms of intraoral cancer lingual cancer is preponderantly a disease of men (87 per cent). The disease tends to occur at an earlier age in women than in men. The sites of origin in the order of their frequency are the middle third of the lateral border (55 per cent), the base (30 per cent) and the anterior third (15 per cent). The point of origin is commonly on the border rather than on the dorsum of the tongue. Apparently chronic irritation is an outstanding etiologic factor in growths of the middle and anterior thirds and it is probable that the chronicity of the irritant is more important than its nature.

Tobacco—One of the most common causes of chronic irritation of the oral mucous membranes is the use of tobacco but since this habit is so common and the degree of indulgence so variable and irregular it is difficult to assess the degree of its influence in the etiology of cancer of the tongue. Over-indulgence in tobacco has been an obvious cause in many instances. The lesser susceptibility of women to intraoral cancer has often been ascribed to a lesser indulgence in the tobacco habit. However if one considers only the non-smokers of both sexes the disease is still more than twice as frequent in men as in women.

Teeth and Artificial Dentures—The most obviously responsible form of dental irritation is the presence of a sharp tooth (broken or worn) or of an ill fitting denture directly in contact with the carcinomatous ulcer.

Syphilis is one of the most important factors in the etiology of lingual cancer largely through its capacity for local manifestations in the form of syphilitic glossitis and its sequelae. The Wassermann reaction will be found to be positive in about one third of the cases of lingual cancer. In most cases the infection has been of long duration (fifteen to twenty years) thus permitting the degenerative tissue changes which follow long standing syphilitic glossitis. Syphilitic infection of short duration is of doubtful etiologic significance since time must elapse for these degenerative changes to take place.

Leukoplakia—In a susceptible subject chronic irritation of the oral mucous membranes (from syphilis or other causes) may result in the development of either leukoplakia or cancer or both. An infiltrating indurated ulcer appearing in a leukoplakic tongue is almost always cancerous.

Pathology—By histologic examination lingual cancer has been found to be epidermoid carcinoma in about 80 per cent of cases. Anaplastic epidermoid carcinoma and lymphoepithelioma are most likely to occur at the base. An adenoid tumor is rare. Sarcoma of the tongue (myosarcoma) is a rare disease and most of the cases occur in infancy.

Symptoms and Clinical Course—In cancer of the anterior two third of the tongue the most common form is an indurated painless non-tender ulcer arising on the edge at the middle third. As it develops the surface usually becomes ruoid, nodular and granular. The ulceration spreads, the induration deepens as the edge of the lesion becomes raised and infiltrated and finally the center becomes excavated. When the growth is 2 or 3 cm. in diameter infection commonly occurs and the lesion may become both slightly tender and painful.

In other clinical varieties the morbid anatomy may differ somewhat. In the papillary form which tends to be less malignant the tumor may fungate over a widely ulcerated area but may fail to infiltrate deeply.

In these cases the mucous membrane at the border of the ulcer is raised and everted, and the ulcerated surface presents an irregular papillary and fissured appearance. In other cases the growth apparently arises in the deep layers of the mucosa or in fissures extending and infiltrating deeply so that a large tumor may occupy the body of the tongue with little or no ulceration or alteration in the surface contour. In the so called scirrhus form the involved portion of the tongue is shrunken. In the later stages of lingual cancer more than one clinical variety may be present so that the entire organ may be infiltrated and boardlike with surface ulceration over an area of only 1 or 2 cm. or the growth may infiltrate deeply from its point of origin and may appear on the surface in one or more additional areas by perforation of the mucosa from below.

Until the disease has infiltrated about a third of the tongue or until a fungating tumor at least 1 cm. in diameter has developed there is little actual discomfort or interference with function. At this stage when the muscles of the tongue have been deeply infiltrated surface necrosis of the tumor and hemorrhage may develop with a marked fetid odor of the breath. The local tumor eventually gives rise to widespread ulceration and sepsis followed by increasing interference with motion, fetor oris, dysphagia, trismus, pain and hemorrhage.

Growths arising in the base of the tongue comprise a definite clinical group. The primary lesion is seldom discovered by the patient. Symptoms referable to the tongue or pharynx are entirely absent in over one third of these patients at the time of admission and if present are likely to be vague and misleading since they consist of slight soreness, dysphagia, hoarseness and dyspnea. A tumor at the base of the tongue may ulcerate and reach a diameter of 3 cm. or more without causing any particularly marked local symptoms. The majority of patients with cancer at the base of the tongue seek advice because of enlarged cervical nodes.

At the base of the tongue the tumor may extend downward into the pharynx as far as the pyriform sinus. The edge of the tongue just opposite or anterior to the tonsillar pillar is a common site of origin of the disease. There is little resistance to extension onto

the tonsillar pillar and the tonsillar region. Cancer of the base of the tongue resembles pharyngeal cancer in general in that the growth tends to be anaplastic carcinoma or lymphoepithelioma. The disease runs a more rapid course and metastases appear earlier and more often below the clavicle. Radio sensitivity is the rule.

Metastases—In cancer of the tongue metastases are more likely to disseminate widely throughout the neck to the lower deep cervical nodes to the posterior triangle of the neck bilaterally or below the level of the clavicle than is the case in growths of the lip or mucosa of the cheek. The lymph nodes earliest and most commonly involved are the upper deep cervical nodes which are centered at about the bifurcation of the common carotid artery. As the disease progresses other nodes may appear usually below this point along the course of the internal jugular vein. If the primary lesion is widely ulcerated or fissured the metastatic lymph nodes are likely to be complicated by secondary infection.

Diagnosis—If cancer of the tongue is suspected a biopsy should be made at the time of the first examination in order to verify the clinical diagnosis. The diseases which may offer some difficulty in the making of a differential diagnosis are in the order of importance syphilis, tuberculosis, superficially ulcerated or fissured leukoplakia and simple granuloma (such as trauma or Vincent's angina).

Gumma of the tongue—the syphilitic lesion most closely resembling cancer in that or gan is rare and occurs less than 1 per cent as frequently as cancer. These two conditions may be difficult to differentiate clinically and a diagnosis of gumma should not be made except after repeated biopsies have failed to reveal the presence of cancer. The most frequent and tragic errors in the diagnosis of cancer of the tongue are due to confusion of this disease with gumma mainly on the basis of a positive Wassermann reaction. A positive Wassermann reaction alone does not disprove the presence of cancer since syphilis and cancer of the tongue co-exist in about 30 per cent of cases. If an ulcer of the tongue is gummatous it will almost invariably heal after two or at the most three weeks of aggressive anti-syphi-

ilitic therapy (neocarphenamine every four or five days) There is no use in persisting with the therapeutic test for a longer period Chronic exfoliative glossitis with the widespread verrucous type of leukoplakia should always be suspected of malignant change

In any case there is no excuse for a temporizing or passive attitude in the presence of a chronic ulcer of the tongue Biopsy examination should be made at the first visit Whatever therapeutic tests may be subsequently indicated in the form of antisyphilitic therapy sodium perborate mouth washes for Vincent's ulcers or the extraction of an offending tooth are not interfered with by taking a biopsy specimen

One normal biopsy specimen does not necessarily prove the presence of cancer The ulcerated surface of a malignant growth may be covered by exuberant simple granulation tissue Therefore if the clinical appearance of the lesion so indicates biopsy should be repeated once or even twice

Tuberculous ulcers unlike gumma frequently occur on the tongue—usually on the dorsum but occasionally on the borders or the tip They usually present a yellowish unhealthy base with little or no overgrowth of tissue as compared to the coarse granular appearance of cancerous lesions Tuberculous ulcers are more likely to be painful and tender with little or no induration A diagnosis is made with the aid of biopsy (preferably repeated) which fails to show the presence of cancer roentgen examination of the chest and examination of the sputum Tuberculous ulcers of the tongue or other oral mucous membrane are almost invariably secondary to demonstrable pulmonary tuberculosis

Benign papilloma of the tongue cannot often be distinguished from the low grade papillary form of cancer except by biopsy Simple granuloma of the tongue due to the trauma of a sharp tooth or an ill fitting denture or to Vincent's infection may be confused with cancer or vice versa Such a lesion should always heal within two weeks after removal of the offending tooth or denture the use of sodium perborate mouth washes or the local application of a solution of neocarphenamine If the ulcer persists longer than two weeks its nature should be definitely proved by biopsy

Other benign lesions of the tongue sometimes confused with cancer include fibroma lymphangioma hemangioma and glossitis rhombica mediana Each of these conditions has definite individual characteristics which should present little diagnostic difficulty

Cervical adenopathy may be the first symptom of lingual cancer and even when the primary lesion is perfectly demonstrable by oral examination the presence of cancer is frequently first discovered by excision of a cervical node for biopsy Strange as it may seem cancer of the base of the tongue may be confused with chronic tonsillitis and tonsillectomy may be performed for the relief of symptoms

Treatment—In the treatment of lingual cancer two separate problems must be considered first the primary lesion of the tongue and second the cervical metastases

General Hygienic Measures—In most instances of cancer of the tongue the hygienic condition of the oral cavity is poor and the complication is always temporarily aggravated by treatment The measures for combating oral sepsis consist of dental hygiene that is cleaning of the teeth by a dental instruction in the use of a toothbrush mouth washes and irrigations The wholesale extraction of teeth should be avoided because of the danger of subsequent osteomyelitis Ordinarily treatment for concomitant syphilis should be postponed until after control of the growth

The primary lesion may arise in areas practically inaccessible from the beginning in surgical removal or the growth even in its early stages may invade such neighboring structures as the floor of the mouth or the tonsillar region so as to make surgical removal both difficult and dangerous For these reasons radiation has become the generally accepted method of choice for the management of the primary lesion in this disease If a small growth arises in the tip of the tongue or fungates from one of its lateral free borders surgical removal may often be accomplished with a fair chance of local cure but ordinarily the method is much less conservative and less successful than radiation Local surgical removal or partial glossectomy is often indicated in conjunction with radiation

Radiation of the primary lesion is ordi-

narily best administered by a combination of external and interstitial radiation (Figs 436, 437). When the lesion is at the base of the tongue, external radiation is given through the skin of each side of the neck by the daily fractionated method and supplemented by radon seeds inserted through the skin of the suprathyoid region in the midline anteriorly. For cancer of the anterior two

ployed in the treatment of lingual cancer by the use of radium or radon needles inserted through the lingual surface into and about the growth. This method has the following disadvantages. It is difficult to maintain the needles in position and there is the possibility of introducing infection through the puncture wounds. The method has the advantage of permitting withdrawal of the

Fig 436—Moderately advanced cancer of the tongue treated by radiation

Fig 437—Advanced cancer of the tongue treated by radiation

thirds of the tongue, external radiation may be advantageously given perorally (through the open mouth) by the use of metal cylinders of proper size, to limit the diameter of the beam and insure its proper direction.¹ After a series of treatments by fractionated radiation by this means, a supplementary dose of interstitial radiation is given by means of implantation into the tumor.

Interstitial radiation alone is often em-

ployed at the completion of treatment, while gold radon seeds must be left in permanently. The most important complication of any form of interstitial radiation of the tongue is radionecrosis, which is probably more likely to result from the introduction of infection and the too intensely localized radiation than from the continued presence of foreign bodies.

The dosage employed in these several

technical methods of radiation is too complicated a subject for discussion in this chapter and these methods should not be undertaken except with thorough knowledge of the biologic effects and physics of radiation.

Partial glossectomy is often indicated in conjunction with radiation or for the management of its local complications. The actual cautery is to be preferred to either the scalpel or endothermy for lingual surgical treatment. The muscular substance of the tongue may be cut through quite rapidly with a small red hot loop of the cautery with almost perfect control of capillary oozing so that the operative field remains practically dry. Only the larger vessels require clamping and ligation. The lingual artery is usually severed deep in the body of the tongue. It should be isolated and clamped before section if possible.

If radionecrosis is not anticipated in the depth of the wound after excision it is not necessary to perform a preliminary ligation of the lingual artery in the neck, but if such a precaution is considered necessary the carotid bulb should be exposed, a local anesthetic being used, and the lingual artery (the second branch) should be identified and tied.

The treatment of cervical metastases in lingual cancer is a serious problem. About 25 per cent of all cancerous cervical metastases come from the tongue. The involvement is likely to be bilateral or to the opposite side from any portion of the tongue. Surgical dissection of the neck is only of limited value in these cases since this necessary radical operation cannot be safely performed soon enough to be of service after recovery from the effects of treatment of the primary lesion. Neck dissection in cancer of the tongue is of value chiefly in cases in which cervical metastases arise several months after apparent control and healing of the primary lesion.

If the metastases are present at the beginning the most successful method of treatment is by radiation which can be carried out safely at the same time as the treatment of the primary lesion. External radiation alone is ordinarily not sufficient except occasionally in the more radiosensitive type of growth originating in the base of the tongue. The average metastasis from lingual

cancer is best treated as a single independent focus of the disease by the application of fractionated radiation through a small cutaneous portal just large enough simply to include the node (3 to 5 cm in diameter) and supplemented by the implantation of interstitial radiation in the form of radon seeds either through skin punctures or after surgical exposure of the outer surface of the node.

Since neck dissection is a major procedure carrying with it a definite mortality it is doubtful whether it is ever justified in the absence of definitely palpable cervical metastases in cases of lingual cancer. The value of prophylactic radiation is also doubtful. The application of small doses (one or two skin erythema doses) to the neck is illogical since that amount of radiation is not lethal for lingual cancer. Cancer lethal radiation doses (six to eight skin erythema doses) to the entire potential metastatic node bearing area of the neck (about 25 by 25 cm on each side) is beyond the limit of tolerance of the local tissues and the body organism as a whole.

Prognosis and End Results.—A recent survey at the Memorial Hospital New York² which included all patients admitted (early recurrent and hopelessly advanced cases) gave a net five year rate of cure for 25 per cent when surgical treatment or radiation or a combination of the two was given as indicated in the individual case.

Cancer of the tongue is not only the most frequent but also the most malignant form of cancer in the oral cavity proper. Under modern methods of treatment (radiation and surgical treatment) the prognosis is best for the younger patients. By these methods the prognosis for women is much better than that for men, probably owing to the fact that cancer in women tends to be more radiosensitive than cancer in men.

In about 55 per cent of the early cases of operable cancer cure is obtained. The prognosis is much better for growths of the anterior two thirds of the tongue. Growths of the base of the tongue carry a relatively bad prognosis because of the rather advanced stage of the disease when it is discovered in this area. The presence of metastases when the patient is first seen makes the prognosis less favorable since it indicates a more ad-

vanced stage of the disease. The histologic form of the growth also influences the rate of cure; the prognosis is low grade epidermoid carcinoma being much better than in lymphoepithelioma or transitional cell carcinoma. Antecedent syphilis does not seem to alter the prognosis to any great extent except that cancer arising on the basis of syphilitic glossitis is likely to be multiple.

SURGERY OF THE NOSE

(Exclusion of Fractures Neoplasms and Sinuses)

General Considerations—For the proper humidification warming and cleansing of inspired air it is necessary that the entire nasal mucosa should function properly. If for any reason the ventilation and drainage of any part of the surface fails troubles ensue. The obstructed area unable to rid itself quickly of dust and bacteria becomes infected. The resulting swelling adds to the obstruction and a vicious circle is established at the same time the remainder of the mucosa unable to cope with the burden of humidifying all of the inspired air becomes dry. This increases the viscosity of the mucous blanket and prevents its being moved along by the cilia not only does it fail to carry away bacteria but it actually becomes a medium for their growth. The attendant irritation ultimately results in hyperplasia which in turn produces definite permanent respiratory obstruction head

ache anosmia and other more remote ills their nature depending on the location of the hyperplasia.

The underlying causes of the original obstruction may be either functional or structural. Among the former are sudden changes of temperature trauma swimming and occupational irritations constipation hunger allergy menstruation and any other conditions conducive to changes in the circulation. The structural causes which are the more important surgically include deviation spurs and abscesses of the nasal septum traumatic changes in the bony structure hyperplasias of the turbinated bodies exostoses partial or complete atresias (usually of the choana) synechiae bony cysts aberrant teeth adenoids and related lymphatic hyperplasias rhinoliths and other foreign bodies.

DEVIATION OF THE SEPTUM NASI

(Deflected Septum)

Definition—An asymmetrical malformation of the nasal septum involving the cartilaginous portion the osseous portion or both producing a deviation from the midline and obstructing one or both nasal chambers to some degree.

Etiology—While in some cases the deviation may be of traumatic origin the asymmetry is ordinarily the result of a redundancy of the structural elements of the septum so that there is a crowding bulging or buckling of this partition within the confining walls of the limiting bones. For this reason the condition is relatively rare in children under the age at which the bony growth of the skull is completed. It is likewise rare in Negroes.

It is probable that the deformity may be due to one of two causes. Either the gothic arch of the infant palate fails to flatten out because of some defect in the development of the maxillary bones thus restricting the space demanded by the growing septum above it or an overgrowth of the septum itself occurs. Straight septums are often found associated with high gothic arches and deviated ones with flat roman arches—evidence in favor of the redundancy theory.

Morbid Anatomy—There are several types of septal deviation (1) a simple unilateral bulge more or less continuous from

top to bottom causing obstruction of one nasal chamber and overpatency of the other (2) an S shaped buckling which obstructs one side above and the other below (3) a lengthy ridge which is a modification of the first type in which the bulge has exceeded the limit of elasticity of the structure and produced a sharp edge (4) an advanced stage of the latter in which there is an actual crumpling of bone and cartilage causing irregular ridges and sulci on both sides and (5) the most common type in which the lower margin of the cartilage is displaced from its groove in the crest of the spina nasalis of the maxillary bone and extending downward beside it makes its appearance in the nostril

Symptomatology—Occurring as they do somewhat fortuitously, these irregularities

of the septum nasi. It may be said of septal spurs that they differ from sharp deviations only in that the opposite surface of the septum remains flat instead of presenting a corresponding concavity the discrepant space being filled with the bony or cartilaginous elements of the structure. Since the symptomatology and the treatment of the two conditions are identical the distinction is academic.

Hematoma and abscess of the septum both causing obstruction are differentiated by their lack of rigidity sometimes even fluctuation on pressure by the history of onset, systemic reactions and blood etiology. Atresias are distinguished by their continuity with the lateral walls although posterior rhinoscopy may be necessary to determine this.

Fig. 438—Typical deviations of the nasal septum: a straight septum; b unilateral bulging; c bilateral buckling; d sharp unilateral ridge; e displacement of the lower edge of the cartilage, which may appear in the nostril; f fracture of the cartilage with overlying bone; and g septal spur.

may obstruct the nasal chamber at any point and to any degree. Consequently the symptoms are those related to the affected part: restricted breathing, obstructed sinus drainage, pressure on nerve trunks or the nasal (sphenopalatine) ganglion, irritation and subsequent hyperplasia of the tissues surrounding the orifice of the auditory tube with diminution in hearing and infection through lack of drainage with attendant exudates (mucoid, purulent or sanguineous depending on the invading organism). It should be borne in mind that the air currents passing through restricted spaces and through over patent chambers may be even more active in the production of inflammation than the pressure of ridges and spurs; hence unilateral symptoms are quite as likely to be encountered on the open side as on the obstructed one.

Diagnosis—There are few conditions which are likely to be mistaken for deviation

Prognosis—Although some deviated septums offer mechanical operative difficulties, the results in experienced hands are uniformly good. Prognosis of the secondary effects of the deviation, such as deafness and sinus disease, depends on the extent of the damage and somewhat on the age of the patient and the recuperative powers of the mucosa.

Treatment—If any treatment at all is required it is necessarily surgical.

Submucous Resection—This ingenious operation was first proposed by Killian and developed by Freer and many others. It is usually performed under local anesthesia. It consists in removing the distorted rigid structures—bone and cartilage—from between the two covering sheets of mucosa without disturbing the latter.

This is accomplished through an incision on one side of the septum—usually the convex extending from the anterior angle of the nasal fossa to the floor just

behind the mucocutaneous junction This incision is made into the cartilage but not through it With a flat elevator the perichondrium is separated from the cartilage and continuously the periosteum from the bone over the entire area of the deviation The original incision is then deepened to include the entire cartilage but not the perichondrium on the other side By pressing on the intact side the edge of the cartilage is presented in the wound where it is readily separated from the perichondrium of the second side The mucosa of this side is elevated over an area to correspond with the opposite one With suitable lifting and cutting instruments the thin sheets of cartilage and bone are removed and the thick bony ridge which is usually found along the floor is removed with a chisel or fractured with strong forceps A light splinting of petrolatum impregnated gauze strips inserted in both nostrils holds the membranous flaps in apposition It should be permanently removed at the end of twenty-four hours Except for careful cleansing no after treatment is required Hemorrhage is occasionally severe This occurs only when the membrane is torn and is controlled by packing If when the membranes are elevated lacerations of both membranes occur at opposing points a perforation of the septum will result This does not ordinarily follow when only one side is torn and the other remains intact although even here infection may intervene and destroy the imperforate side A perforation is of no great consequence and the patient is usually not aware of it unless it happens to be small circular and anteriorly placed in which case it produces a whistling sound during breathing The remedy is to lengthen the opening posteriorly to form a slit which will not produce a whistle Large anterior perforations gather secretions which dry and form exceedingly annoying crusts Hematoma and abscess of the septum are more serious complications of the septum operation

HEMATOMA AND ABSCESS OF THE SEPTUM

Definition—A collection of blood or of pus beneath the perichondrium or the periosteum in the intact septum or between the opposing membranes following a submucous resection

Etiology—Hematoma of the septum is usually the result of trauma and while it was formerly encountered chiefly in children the automobile now distributes it impartially to all ages It occurs after a submucous resection, more frequently in those carefully performed operations in which no tears occur and the incision is closed and splinted Some operators habitually slit the membrane along one side of the floor of the nose at the finish of the operation if no tear has accidentally been made to guard against the retention of blood If the hematoma becomes infected an abscess occurs

Diagnosis—These conditions are usually bilaterally obstructive They may be readily diagnosed by palpation if their appearance leaves any doubt Fever, local heat and swelling and the accompanying leukocytosis announce the infection of the hematoma and the onset of the abscess

Prognosis—If left untreated they may result in deformity, either in a thickening of the septum or in the case of the abscess in a destruction of the cartilage of the nasal ridge producing a 'saddle nose' Cases of meningitis have been reported following septal abscess

Treatment is the same in both cases—Free incision near the floor of the nose It may be necessary to maintain drainage for several weeks by means of a strip of gauze laid into the wound which should not be permitted to close until all likelihood of recurrence is past Irrigation of the cavity is commonly frowned on as it may result in further elevation of the membrane and extension of the process Sulfonamides by mouth are useful

NASAL HYPERPLASIAS (Chronic Hyperplastic Rhinitis)

Etiology—Constant local irritations the result of badly disturbed breathing industrial fumes and dusts or infection of a neighboring sinus eventually produce a thickening of the epithelium and a fibrosis of the tunica propria especially in the erectile portions of the turbinal mucosa Here elsewhere the connective tissue is laid down along the vascular channels and the uneven contraction of this tissue produces corrugations and irregularities of a membrane already thickened and swollen These hyperplasias often interfere with respiration sinus drainage or the ventilation of the auditory tubes Not infrequently the underlying periosteum and bone are involved in the process

Symptoms—The symptoms are those of nasal obstruction pressure and sometimes pain varying with the extent and location of the hyperplasia

Treatment is preferably preventive The early correction of deformities and the eradication of infections by removal of the irritating cause prevent the progress of in

flamation to the hyperplastic stage According to Wright the formation of actual fixed connective tissue requires much longer and occurs much later than is ordinarily supposed

After the fibrosis becomes established however the treatment must consist of destruction or removal The first may be accomplished with the actual cautery or a high frequency cautery It is possible with a properly insulated needle electrode to confine the destruction to the submucosa thus preventing the scarring of the ciliated epithelium The usual method of removal especially when bone is involved is with chisel and snare or with one of the many punch forceps designed for the purpose

ATRESIA NASI

This is a comparatively rare condition It may be the result of syphilis lupus or injury but is usually congenital The anterior atresias are membranous Posterior atresias occurring slightly ventral to the choanae may be either bony or membranous or a combination of the two They may be bilateral or unilateral and cause little trouble and may remain long undiagnosed if unilateral

The treatment is operative and is often unsuccessful

ABSCESSSES ABOUT THE NOSE (ALA COLUMELLA AND LIP)

These abscesses should be mentioned particularly in order to stress the importance of their proper treatment Although it would seem that the venous drainage of the superficial portions of the nose should be through the anterior facial veins plexuses and communicating veins actually form a fairly direct tract through the ophthalmic veins from the forehead the external nose the cheeks and both lips to the cavernous sinus

Abscesses in these parts should be treated with hot fomentations and the patient should be confined to bed Incision should be avoided Numerous fatalities have followed incisions cavernous sinus thrombosis having occurred Early and judicious use of penicillin or sulfonamides is indicated if the

is at all severe

EPISTAXIS

Epistaxis occurring spontaneously is almost invariably due to rupture of small superficial vessels of the septum overlying the inferior anterior portion of the septal cartilage These are often so near the nostril that first aid may consist only of grasping the nose and compressing it until the bleeding stops The bleeding vessel is destroyed by touching it with a chromic acid head or the actual cautery If the hemorrhage obscures the bleeding point it is advisable to insert *lightly* into the nostril a cotton pledget moistened with epinephrine (1:1000 solution) for a few minutes Forceful picking may only widen the tear and increase the bleeding It should be resorted to only for a severe hemorrhage in which case anterior packs and postnasal plugs should be inserted

If hemorrhage however scant cannot be completely and permanently controlled one of the following conditions should be suspected adenoids vascular hepatic and renal disorders purpura hemophilia luetic end arteritis neoplasms exanthemas The existence of vicarious menstruation as such is extremely doubtful although women subject to no bleed from other causes are apt to bleed during or just prior to the menstrual period

ARTHUR W. PROFTZ

INFECTIONS OF THE NASAL ACCESSORY SINUSES

Etiology—The etiology of inflammatory disease of the nasal sinuses is embraced to a certain extent in those conditions which interfere with the drainage and ventilation of the cavities The obstructive lesion may be a deflected septum an enlarged or cystic middle turbinate a nasal polyp or some other nasal tumor a foreign object or enlarged adenoids

The sinuses may become infected even when the drainage and ventilation are normal if the body resistance is unduly lowered and there is a tonsillar or nasopharyngeal infection Patients suffering from an allergic rhinitis frequently have a secondary sinusitis The maxillary antrum may become involved from caries of the root of a tooth located beneath the floor of the antrum

Pathology—The pathologic changes

which occur in the mucous membrane and bony walls of the sinuses during the course of an infection are the same as would occur in any mucus-lined cavity. These changes may be described as acute congestive, acute suppurative, chronic suppurative and chronic hyperplastic. Chronic suppurative changes may be (a) edematous, (b) granular or infiltrating, (c) fibrous or (d) a mixture of any or all of these. Connective tissue changes are common with much thickening of the subepithelial layer. Polypi which may occur in any of the sinuses are more frequently found in the maxillary or ethmoid sinuses and would be classified as a chronic hyperplastic form of sinusitis. The hyperplastic form of sinusitis is usually secondary to an allergic rhinitis. Ulceration of the mucosa with involvement of the underlying bone takes place particularly in the chronic form of sinusitis.

Symptoms and Diagnosis of Sinus Infections.—Pain and headache referable to the region of the involved sinus are usually present, particularly when the frontal or maxillary sinuses are acutely involved. In acute ethmoiditis the discomfort may be described as a sense of fullness or pressure between or above the eyes. In acute sphenoiditis the headache may be vaguely deep-seated in the head, or the pain may be referred to the occipital or frontal regions. Acute frontal sinus pain is usually of the periodic type, that is, it may start in the morning and leave in the afternoon permitting the rest of the day and the night to be spent in comparative comfort. In chronic sinusitis there is usually an absence of pain; however, headache may be complained of occasionally but may not be referred to the affected sinus except during an acute exacerbation.

Tenderness and pain on pressure over the involved sinus is usually present in the acute form but as a rule is not found in the chronic form.

Redness and swelling may be present over any of the acutely involved sinuses that are contiguous to the skin. These symptoms are frequently present at the inner angle of the orbit in acute ethmoiditis in infants and children. Edema may be present without other signs of inflammation.

Nasal Discharge.—The presence of pus or

mucopus in the nasal chambers is usually significant of an infection within one or more of the sinuses. Pus in the middle meatus signifies involvement of the frontal, anterior ethmoid or maxillary sinus. Pus which emerges above the middle turbinate is suggestive of posterior ethmoid or sphenoid involvement. Pus may not be present in hyperplastic sinusitis.

In chronic sinusitis or in mild acute sinusitis the volume of discharge may be so slight as to produce only a postnasal dis-

Fig. 439.—Transillumination of the antrum. The patient's right side is normal; i. e., the pupillary reflex and crescent of light are present. The left side is diseased.*

charge. The patients frequently call this a "dropping in the throat." The movement of the cilia of the nasal mucosa normally propels the secretions toward the posterior nares.

Transillumination affords valuable information as to the condition of the maxillary and frontal sinuses but none in regard to the sphenoid and ethmoid sinuses.

In transillumination of the maxillary antrum (Fig. 439), a Preer-Jackson transil-

* Ballenger: Diseases of the Nose, Throat and Ear, Lea & Febiger Publishers.

luminator is placed in the mouth (in a dark room) with the lips closed. If the antrum is normal three signs will be noted: (1) The infraorbital crescent of light corresponding roughly to the lower portion of the lower eyelid will be seen. (2) The pupil of the eye will appear red. (3) The patient will perceive a sense of light when the eyes are closed. If the red pupillary reflex and the crescent of light are absent the antrum is probably affected. However, a thickened mucosa from a former infection, tumor formation or thick bones may obstruct the passage of light. A dental lamp may be placed also above the infraorbital ridge just below the eyeball and the glow of light looked for in the roof of the mouth.

Transillumination of the frontal sinus is accomplished by placing a hooded light under the floor of the frontal sinus at the upper and inner angle of the orbit and comparing the two sides. Variations in the amount of transillumination obtained will depend on any pathologic condition present, the size of the sinuses and the thickness of the bones through which the light must pass.

Röntgenography of the sinuses will give suggestive evidence as to the size and shape of the sinuses and of the absence or presence of any pathologic condition. A diagnosis should not be made from the films alone but when correlated with the clinical examination a reasonably accurate opinion may be formulated. The injection of iodized oil into the various sinuses followed by roentgenography gives valuable supplementary information, particularly in regard to the thickness of the sinus mucosa, polypoid degeneration and tumor formation.

Complications of Sinusitis—Extension of the infection from the sinuses to other parts of the body may occur: (1) by a thrombophlebitis of the perforating veins; (2) by way of a dehiscence through the sinus wall; (3) by direct extension through an ulcerating or necrotic area of the sinus wall; and (4) through the vascular channels in the form of bacteremia.

Optic neuritis and retrobulbar neuritis and other inflammatory diseases of the eye and adnexa are occasionally due to sinusitis, particularly when there is involvement of the sphenoid and ethmoid sinuses. The optic nerve may be involved by direct extension

of the inflammation by vascular congestion or by pressure on the optic nerve produced by osteitis or periostitis. In addition to these direct involvements, loss of vision as a result of sinusitis may be due to toxemia or bacteremia as seen when the sinus acts as a focus of infection. Hyperplastic sinusitis is not in itself a direct cause but as a predisposing factor it is of much importance. Multiple sclerosis is the most important cause of retrobulbar neuritis and should be excluded before operative intervention is undertaken in the sinuses.

Orbital Cellulitis and Abscess from Sinusitis—Infections of the ethmoid and maxillary sinuses are the most frequent causes of orbital cellulitis and orbital abscess. This is especially true during childhood when most of these orbital infections are seen. In children certain anatomical factors may be present which enhance the development of orbital complications, such as congenital dehiscences along the ethmomaxillary suture in the lamina papyracea or in the orbital wall of the maxilla. Another factor is the more profuse development of the vascular system in children, thereby facilitating the entrance of infection from the sinuses into the orbit as a thrombophlebitic process. Infection may gain entrance into the orbital cavity also by perforation of the bony sinus wall. The pus in some cases does not perforate into the orbital cavity but may be guided anteriorly by the periorbita to the eyelids where it may rupture spontaneously. The pus may also burrow along the periorbita to the sheath of the optic nerve and result in intracranial involvement. An extension of thrombophlebitis of the orbital vein into the cavernous sinus will result in cavernous sinus thrombosis.

The symptoms of these orbital infections secondary to sinusitis are increasing edema of the eyelids with or without chemosis and limited extraocular movements. Proptosis may be present either with or without the formation of an abscess. Changes in the fundus may be present in some cases.

Conservative treatment including use of the sulfonamides as indicated, hot compresses, tampons or sprays of ephedrine and mild suction will cure most cases of orbital cellulitis. Operative intervention is necessary in some cases if pus is thought to be

present or if the child's condition is becoming progressively worse (see paragraph on the external drainage of the ethmoid)

Osteomyelitis Secondary to Sinusitis—This complication is usually due to the *Staphylococcus aureus*. The *streptococcus* has been reported in a few cases and the *pneumococcus* rarely. About half the reported cases are found in adolescents and young adults. The spread of the infection is usually by hematogenous metastasis especially as thrombophlebitis of the venous system into the bones of the cranium through the anastomosing diploetic veins on the under surface of the cranium or the frontal sinus but may be directly upward through the diploë to the vault of the skull. Isolated areas of infection may be found in various portions of the skull. The outer table of the skull is usually the first to break down with the formation of a subperiosteal abscess. Intracranial involvement may result from a breaking down of the inner table. The symptoms are those of a low grade sepsis and the appearance of the soft doughy swellings (Pott's puffy tumors) over the vault of the skull. The diagnosis is established by means of roentgenograms.

Penicillin (when available) should be given in adequate amounts intravenously, intramuscularly or topically. The sulfonamides especially sulfathiazole should be tried being given by mouth as well as applied locally in the form of powder to the exposed areas.

In the acute and rapidly spreading type of osteomyelitis all methods of treatment may fail. In the slowly developing and more or less chronic cases probably the best treatment is wide resection of the affected areas.

Acute osteomyelitis of the superior maxilla in infants is occasionally seen. Some cases appear to be secondary to a buccal infection others may be due to a maxillary sinusitis.

Treatment of Sinus Infections—The local treatment of sinus infections consists in establishing free drainage and ventilation of the sinuses. Instilling or spraying ephedrine or placing tampons of ephedrine in the region of the middle turbinate gives temporary relief. Mild suction cautiously applied is of benefit in many cases especially after the first stage of acute congestion is over. Proetz's displacement technique in which

intermittent negative pressure is used to fill and irrigate the sinuses especially the posterior ethmoids and sphenoids with a 0.25 per cent ephedrine solution is a helpful therapeutic procedure in obstinate cases. The technique may be used also as a diagnostic measure radiopaque oil being injected into the sinuses and the emptying time determined by means of subsequent roentgenograms. Some form of heat is of great comfort during the painful stage. General supportive and symptomatic medication should be given as required. In acute sinusitis with fever chemotherapy will be of decided benefit in most instances. Chemotherapy is seldom required in chronic sinusitis except during acute exacerbations.

Irrigation of the Sinuses—Irrigation of the maxillary sinus is of decided benefit in the acute stage after the febrile stage has passed. This may be accomplished through the natural ostium in a large majority of cases by means of Pierce's antrum cannula. If marked inflammation in the region of the middle turbinate is present if force is required to insert the cannula beneath the middle turbinate or if the maxillary sinusitis is accompanied by a frontal sinusitis it is the writer's practice to gain entrance to the antrum beneath the inferior turbinate by puncturing the nasointral wall with a suitable antrum trocar. Irrigating with a saline or a 2.5 to 5.0 per cent suspension of one of the sulfonamides in a saline solution two or three times a week is of decided benefit.

Irrigations of the frontal sinus may be performed through the frontonasal duct except in those cases in which an obstruction exists such as an enlarged middle turbinate or a deflected septum. However the necessity for irrigating the frontal sinus is not so frequently indicated as in the case of the maxillary antrum because of the dependent drainage of the frontal sinus.

Irrigation of the sphenoid sinus is practiced both as a diagnostic measure and as a therapeutic means of relief. If an obstruction is present it may be necessary to remove it by some surgical procedure before the irrigations can be effected. Irrigations of the sphenoid sinus are usually given through the natural ostium but in some instances perforation of the anterior sphenoidal wall is necessary.

Irrigation of the ethmoid sinus is not possible except by Proetz's displacement method however a somewhat similar result is obtained by placing tampons of a mild colloid silver in the middle meatus and leaving them in place for twenty or thirty minutes. The hygroscopic and mild antiseptic action of the silver salt produces a free outpouring of the nasal secretions which is of decided benefit in cases of subacute or chronic ethmoiditis.

The surgical treatment of sinus infections consists in the removal of any existing obstructive lesions and in some form of intranasal or extranasal surgical procedure.

Removal of Obstructing Lesions—Obstructing lesions which necessitate removal are enlarged cystic or impacted middle turbinates, high deflections of the nasal septum, nasal polypi or other nasal tumors which may obstruct the normal sinus drainage, foreign objects within the nasal cavities and enlarged adenoids. As the correction of these lesions is discussed elsewhere in this volume further consideration will not be given here except to state that in many cases of sinusitis a satisfactory recovery will follow the correction of the obstructions.

Surgery of the Maxillary Sinus—*Removal of the Nasoantral Wall (Antrum Window)*—In many cases of subacute or chronic maxillary sinusitis favorable results will follow the intranasal removal of the nasoantral wall. After local anesthesia is established the nasoantral wall is punctured in its central portion by means of a Good or Thompson antrum trocar rasp. The same rasp is used in enlarging the opening to a sufficient size to permit the introduction of the Wagner or some similar type of biting forceps. Care should be exercised to avoid injuring the lacrimal canal which opens beneath the anterior end of the inferior turbinate. If the bony floor or other portions of the maxillary sinus are carious from dental infection a properly bent curette may be introduced through the nasoantral opening and the involved portions gently curetted. Packing is necessary only to control excessive bleeding.

The Caldwell-Luc Operation—In some instances of chronic maxillary sinusitis with extensive polypoid cystic or hyperplastic changes in the mucous membrane it is ne-

cessary to supplement the intranasal removal of the nasoantral wall with an additional opening through the canine fossa. This external opening which is made under the upper lip through the canine fossa permits direct inspection of the sinus and facilitates the removal of all or only the diseased portions of the mucosa. The periosteum is elevated over the canine fossa and retracted. The anterior bony wall is penetrated by means of a gouge and mallet. The opening is enlarged with the gouge and rongeur forceps. The cavity is explored and the diseased mucosa particularly over the floor is elevated and removed. Packing is required only for excessive bleeding.

Surgery of the Frontal and Ethmoid Sinuses—*Intranasal Drainage of the Frontal or Ethmoid Sinuses*—In those cases of chronic frontal or ethmoid sinusitis in which local treatment and the removal of any obstructive lesions have not effected a cure or an amelioration of the symptoms some form of intranasal surgical drainage may be indicated particularly if the patient shows signs of sepsis or has frequent pains or headaches. A roentgenologic study of the sinuses should be made to determine the dimensions and pathologic condition present before any surgical procedure is instituted.

Some type of operation is described by Moshier is frequently employed. This combines the removal of all or in some cases the anterior portion of the ethmoid cells together with the enlargement of the frontal ostium.

External Drainage of the Frontal Sinus—In a few cases of frontal sinusitis with external fistula, intracranial or orbital complications or excessive bone necrosis with unusual or extensive development with orbital extensions or with infected ethmoid cells extending over the roof of the orbit some type of external drainage may be required. The simplest of these external operations consists in removal of the anterior wall with external drainage. If necessary the lining mucosa is removed. Usually some disfigurement results. Lynch's frontoethmoid operation is perhaps the safest external operation to use as entrance to the frontal sinus is through the floor thus minimizing the danger of extension of osteomyelitis to the frontal bone. Furthermore less disfigurement results. In the Hajek-Luc operation the anterior wall

of the frontal sinus is removed septums if present are broken down and the diseased mucosa curetted. The frontonasal canal is enlarged through the floor of the frontal sinus and the anterior ethmoid cells are removed so as to establish as free drainage from the frontal sinus as possible. In rare instances a radical external approach to the combined frontal ethmoid and sphenoid sinuses is indicated.

External Drainage of the Ethmoid—Frequently in a case of orbital abscess or of an ethmoid fistula opening near the inner angle of the orbit it is advisable to enter the ethmoid labyrinth by an external route. An incision is made through or just below the inner portion of the eyebrow extending around the inner canthus to the lower portion of the medial orbital wall. Access to the labyrinth is obtained through the naso-orbital wall and the cells are curetted through this opening. The orbital contents should be investigated and pus drained if present. External drainage is maintained until the discharge ceases.

Surgery of the Sphenoid Sinus—*Removal of the Interior Sphenoid Wall*—Drainage of the sphenoid sinus consists in removing the anterior wall. Local anesthesia is usually sufficient. As a rule the preliminary removal of the middle turbinate is necessary to obtain room for working when the intranasal method is used. A sphenoid punch forceps is inserted through the sphenoidal ostium and the opening enlarged in a downward and outward direction. If the lining mucosa is curetted great care should be taken to avoid injuring the numerous nerves and vessels in close proximity to the mucosa. Dehiscences in the bone should be watched for assiduously.

SURGERY OF THE EAR

Congenital Deformities—The most common congenital deformities are microtia in which the ear is very small, macrotia in which there is a large auricle with sometimes an accessory projection, lop ears which protrude at a right angle to the skull, excessive enlargement of the lobe, complete or partial stenosis of the external auditory meatus and complete absence of the external ear.

Injuries—Many types of injuries to the external ear occur both in war and in civil life. In the latter automobile accidents play the leading role. To remedy defects plastic operations may be attempted and if complete loss of an auricle occurs a prosthesis may be held in place by spectacles.

Othematoma—A suffusion of blood between the cartilage and the perichondrium due to trauma is called an othematoma. It is frequently seen in boxers. In the acute stage the fluid blood may be aspirated and pressure applied to prevent further bleeding. Great care must be exercised to prevent infection. If a clot has formed an incision should be made, the clot turned out and pressure applied. If this is neglected great permanent deformity frequently results. If infection takes place between the cartilage and the perichondrium the abscess should be drained and the cavity treated antiseptically. Otherwise necrosis of cartilage soon takes place and fibrosis occurs with the resulting cauliflower ear.

Neoplasms—A number of benign tumors such as fibromas, osteomas and occasionally chondromas may occur usually in the external canal. Of the malignant tumors epithelioma is the most common but endothelioma and sarcoma may be encountered. Epithelioma of the auricle is often not highly malignant in its course unless invasion of the adjacent structures occurs. The treatment consists in operative removal or still better in many instances the application of roentgen rays, radium or surgical diathermy.

Foreign Bodies in the Ear—Foreign bodies of all kinds may be inserted into the

external auditory canal especially by children and the insane. If they are forced beyond the isthmus of the canal their removal is difficult. Some substances tend to swell when moisture enters the canal while others by pressure cause erosion of the skin of the meatus or perforation of the drum membrane. The removal of foreign bodies as well as inspissated cerumen must be undertaken with great care lest by use of instruments injury to the canal or perforation of the drum membrane results with consequent infection of the middle ear. A stream of warm water carefully directed toward the superior wall of the canal will sometimes dislodge a foreign body and cerumen can almost always be removed in this manner. It may be softened by means of glycerin or oil before the syringing. At times the substance such as a pebble is in contact with the drum membrane so that a retroauricular incision must be made in order to extract it. Insects should first be made quiet by the use of chloroform vapor alcohol oil or kerosene and then removed with forceps or by syringing.

INFECTION OF THE EXTERNAL EAR

Otitis externa may be either circumscribed in the form of furuncles or diffuse often as a result of infection with *B. pyocyaneus*. The chief symptom is pain in and around the external canal with three special points of tenderness elicited by (1) pressure on the tragus (2) manipulation of the auricle and (3) pressure on the infra-auricular gland.

Treatment—For the circumscribed form of otitis heat should be applied the canal packed with ichthyol yellow oxide of mercury ointment or aluminum acetate and the furuncle incised only when fully developed. For the diffuse form oxidizing agents such as hydrogen peroxide potassium permanganate etc. should be avoided as *B. pyocyaneus* is oxygenophilic. Packs of 3 or 5 per cent silver nitrate should be used. In either form pain may be relieved by from 5 to 10 per cent phenolglycerin applied to the external auditory canal. Sedatives are often necessary. In the diffuse form surgical intervention is contraindicated. Vaccines are often found to be helpful in preventing recurrence.

INFECTION OF THE MIDDLE EAR

Acute Otitis Media—**Etiology**—The middle ear is usually involved by way of the eustachian tube following infection of the nose nasopharynx or pharynx. Occasionally infection occurs via the external auditory canal either as the result of perforation of the drum membrane by a foreign body or by entrance of water or some other substance through an old perforation. Rarely is the infection of hematogenous origin from a distant focus.

The **symptoms** are pain in the ear (sometimes accompanied by headache) fever and a diminution in hearing.

Treatment—For the relief of pain from 5 to 10 per cent phenolglycerin heat and sedatives are used.

Paracentesis—For relief of pressure and retention myringotomy (paracentesis of the drum membrane) is necessary the indications being:

I Light symptoms (1) pains in the ear which defy other remedial measures (2) reduction in hearing (the whispered voice heard less than 1 to 2 meters away) and (3) bulging or redness of the drum membrane. If any two of these symptoms are present myringotomy is required.

II Important or grave symptoms. The light symptoms plus (1) fever (2) headache and (3) mastoid tenderness. If any one of these additional symptoms is present myringotomy should be performed. The drum membrane should be incised at the point of greatest bulging but the most favorable location is in the posteroinferior or the anteroinferior quadrant.

Complications of Acute Otitis Media—The most often observed complications are acute mastoiditis lateral sinus phlebitis or thrombosis petrositis sepsis and meningitis.

Acute mastoiditis is usually due to extension of the infection to the mastoid antrum and other mastoid cells. There are four types of mastoid process (1) the pneumatic in which the cells or air spaces (lined with mucous membrane) extend from the antrum to the tip and often to the posterior border of the mastoid (2) the diploic in which there are diploic spaces (marrow spaces) but no pneumatic cells (3) the mixed type in which some parts are pneu-

matized and others are diploic, and (4) the type in which the mastoid process is composed wholly or in large part of hard com-

middle ear or mastoid infection. The symptoms of pain and tenderness may be present within a few days after the onset of the

Fig 440—Diagram showing the structures of the middle ear

Fig 441—Diagram showing relationship of important structures in the region of the middle ear

pact bone ("sclerotic" type) with few if any, air or marrow spaces. This type is often the end result of repeated or long-continued

acute otitis media, but this does not mean that changes requiring surgical intervention are necessarily developing. Decalcification

of the bony trabeculae usually requires from one to three weeks in certain types of virulent infection the breaking down of these trabeculae may occur much earlier.

The *symptoms* vary greatly in number and severity. Usually there is some *pain* to the mastoid process. When the infection reaches the outer cortex and involves the periosteum there is tenderness. This is likely to appear early and to be well marked in childhood when the cortex is thin and conversely it is often absent in advanced age when the cortex is thick and hard. The usual points of tenderness are (1) the region of the mastoid antrum (2) the tip especially if there is a large terminal cell and (3) the posterior border of the mastoid process. Varying degrees of *fever* may be present especially in children but in adults it is rarely high or of an intermittent character unless the inflammatory process involves the vicinity of the lateral sinus or other veins. *Chills* especially when followed by a sudden high rise in temperature with a rather abrupt drop are usually significant of a pathologic condition in or near the lateral sinus. In children however the same symptoms may be due to involvement of small veins present throughout the mastoid process and not the lateral sinus itself. When the inflammatory condition affects the cortex and periosteum some *swelling* or infiltration is usually noted. *Edema* is often present and may appear at an early stage in young children. It is at times due not to the involvement of the mastoid itself but to a furuncle on the posterior wall of the external auditory canal. *Sinking* or *sagging* of the posterosuperior wall of the bony portion of the external auditory canal is usually considered an indication for a simple mastoid operation. If fistula of the mastoid cortex occurs the escaping pus elevates the periosteum and fluctuation is present. It must be remembered that in infants with an open petrosquamosal suture a *subperiosteal abscess* may develop without destruction of bone.

Treatment—The opening of the mastoid antrum (antrotomy) and the removal of all infected or diseased bone is the surgical treatment. The proper administration of the sulfonamides has greatly reduced the incidence of mastoiditis.

Indications for *simple mastoidectomy*

(antrotomy) vary with different otologists but include profuse purulent discharge continuing for from three to six weeks persistence of fever or pain from the onset of the disease or recurrence after subsidence in the first week sagging of the bony external canal wall swelling of the soft tissues over the mastoid subperiosteal abscess marked diminution in hearing paralysis of the facial nerve and any pyemic or cerebral symptoms not due to infection elsewhere.

Technic of Antrotomy General anesthesia is usually employed but local anesthesia may be used in severe cases of diabetes cerebri etc. An incision is made about $\frac{3}{4}$ inch posterior and parallel to the insert on of the auricle and the periosteum is elevated. With a gouge or an electrically driven burr the cortex is removed and the antrum located. All softened bone and granulations are removed not only in the antral region but in the zygomatic root the mastoid tip and behind the lateral sinus. If the bone covering the lateral sinus or dura is softened it should be removed. Even if the bone is apparently normal the sinus should be uncovered and investigated if there have been chills intermittent fever or any other symptoms indicating the possibility of an infection in or about the lateral sinus. After all pathologic tissues have been removed the wound is lightly packed with plain gauze iodoform gauze a cigarette drain or gauze saturated with 5 per cent sulfanilazole ointment or the wound is dusted or even loosely filled with one of the *Monamide* powders and then closed with sutures or clips except for a small space at the lowest point through which the packing projects. Most otologists surgeons prefer to remove all cell-bearing areas whether or not they are objectively affected at the time and the operation is not considered complete until this has been done.

LABYRINTHITIS

Etiology—Primary labyrinthitis is due to trauma etc while secondary suppurative labyrinthitis is due to infections of the inner ear via the middle ear during either acute or chronic otitis media. Usually the cochlea and vestibule are both involved. Clinical varieties include (1) circumscribed (2) serous and (3) diffuse purulent labyrinthitis.

Symptoms—In circumscribed labyrinthitis there is often the fistula symptom and if the stage of irritation is present there is nystagmus to the diseased side. In serous labyrinthitis there is usually nystagmus to the diseased side marked diminution in hearing and vertigo. In diffuse suppurative labyrinthitis there is always complete loss of hearing in the affected ear complete ab-

sence of vestibular reactions, nystagmus to the well side, marked vertigo, fever (usually) and development of meningitis (often).

Treatment—For circumscribed labyrinthitis which occurs usually in chronic otitis media, radical mastoidectomy is performed without disturbing the fistula in the semi-circular canal. For serous labyrinthitis, complete rest but usually no operation is needed, aside from a myringotomy or simple mastoidectomy, when other indications for these operations are present. In diffuse suppurative labyrinthitis, if there is high fever or any sign of meningeal irritation, radical mastoidectomy and opening of the labyrinth are necessary. There are various types of labyrinth operations, such as the Denmann, Hirschberg, etc. The cochlear and vestibular portions of the inner ear are opened to effect drainage. Unless symptoms of imminent intracranial involvement are present, labyrinth drainage is most safely done during the latent period that follows the subsidence of the acute symptoms.

CHRONIC OTITIS MEDIA

Etiology—A case of acute otitis media may become chronic because of (1) some pathologic conditions in the nose, pharynx or nasopharynx, such as sinus infection, adenoids, or infected tonsils; (2) disease of the eustachian tube (atresia); (3) disease of the mastoid cells (not involvement in the early stage of acute otitis media, which usually subsides); (4) disease in the petrous pyramid, such as parabyrinthitis; (5) systemic disease, such as tuberculosis; (6) mixed infections of the middle ear; and (7) severe acute infectious diseases, such as scarlatina, measles, diphtheria, etc.

Symptoms—The most common symptom is the purulent secretion, which is often fetid because of the necrosis of bone. Sometimes the ear is dry except when acute exacerbations occur. Hearing is usually impaired, especially for the low tones. Pain is usually present only at the time of the acute exacerbation or when there is necrosis of the bone, which is in proximity to the dura. Cholesteatoma is present in many cases with marginal perforations.

With central perforation, involvement of bone and likewise intracranial complications are rare. In this type of case there is often

mucopurulent secretion due to infection via the eustachian tube, which rarely calls for surgical intervention. Marginal perforation involves the bone, often causes serious complications and is the type that usually requires operation.

Treatment—(A) *Non Surgical*—If the secretion is mucopurulent, suggesting involvement of the eustachian tube, the nasopharynx should be treated, the adenoids removed, etc. The use of 50 or 75 per cent alcohol or pure ether in the middle ear is often of some benefit. Granulations may be cauterized with trichloroacetic acid, chromic acid or silver nitrate, or they may be removed surgically. With perforation in Sharpnell's membrane and involvement of the attic, irrigation with dilute alcohol is indicated, but if there is no improvement after a reasonable period, radical mastoidectomy must be performed. If a large perforation is present with only a small amount of secretion, boracic or iodine powder should be insufflated. Whenever a perforation is present, it should be remembered that no water should at any time be allowed to enter the ear because of the danger (1) of reinfection of the middle ear or (2) of a caloric reaction with consequent vertigo.

(B) *Surgical Treatment*—(1) *Ossiculectomy* is occasionally performed in cases of necrosis of the ossicles accompanied by moderate suppuration and in properly selected cases this obviates the necessity for a more radical procedure. Later (2) *Radical mastoidectomy* is necessary when the following are noted: (a) marginal perforation especially in the posterosuperior quadrant of the drum membrane with necrosis of bone; (b) cholesteatoma; (c) a persistent fetid purulent discharge; (d) repeated acute exacerbations of a chronic otitis media; and (e) intracranial complications.

Technic of Radical Mastoidectomy—The theory of radical operation in chronic otitis media is to eliminate all areas of infection in the middle ear and mastoid process and to convert the middle ear, mastoid antrum and cells and the external auditory canal into one continuous cavity. An incision is made about 1 or 2½ inch posterior and parallel to the insertion of the auricle. The periosteum is reflected not only over the mastoid process but over the posterior and upper wall of the bony external canal. The cortex is entered either with a gouge or with an electrically driven burr and the antrum located, great care being taken to avoid the

external semicircular canal and the facial nerve which lies just below it and above the oval window. The so-called "bridge" (the outer half of the inner end of the posterior wall of the bony external auditory canal) is removed, converting the middle ear (the antrum and the external auditory canal) into one cavity. The so-called "facial spur" (the posterior bony canal wall) is cautiously leveled down as far as possible without injury to the facial nerve. All granulations and necrotic bone are carefully removed from the antrum, attic and middle ear. Great caution must be observed in curetting the latter to avoid injury to the footplate of the stapes for fear of causing acute labyrinthitis and consequent meningitis. To prevent reflections of the middle ear by way of the eustachian tube, its tympanic end should be curetted to produce closure, but injury to the internal carotid artery, which lies in close proximity, must be avoided. After careful inspection of the whole cavity, a plastic procedure is done on the membranous portion of the posterior wall of the external auditory meatus. Sulfathiazole ointment packing is inserted via the canal after the wound has been dusted with one of the sulfonamide powders or the entire cavity may be loosely filled with the powder and only enough gauze packing used to keep the plastic flaps in position. Then the retroauricular wound is sutured. If the lateral sinus lies far forward so that the approach to the antrum is very difficult or impossible by the usual route, the Stacoe operation, which seeks the antrum by way of the external auditory canal, must be employed.

The operative results are judged from three standpoints: (1) Secretion. If the whole cavity is ultimately lined with epidermis the cavity will be dry in a considerable percentage of cases; however (as high as 30 per cent) some secretion persists. (2) Hearing. If the impairment of hearing before operation is very great, much improvement rarely occurs; sometimes the hearing is even worse after operation. (3) Prevention of intracranial complications. If the operation is properly performed this purpose is usually achieved.

Complications of chronic otitis media usually occur at the time of acute exacerbations, but they may develop during acute otitis media without any previous attack.

Lateral Sinus Thrombosis—Involvement of the lateral sinus may appear as a perisinus abscess, phlebitis or actual thrombosis within the lumen.

Symptoms—(1) A sudden high rise in temperature accompanied by a chill and then an abrupt drop to normal or subnormal. (2) Marked leukocytosis, especially an increase in the polymorphonuclear leukocytes. (3) Edema over the posterior portion of the mastoid process if the emissary vein

is involved and (4) embolism which often occurs and affects the joints, heart muscle, lungs or other parts of the body.

Diagnosis—Pneumonia and other causes of pyemia as well as malaria must be excluded. The Tobey-Ayer test is often of value in determining whether or not occlusion is present. It is also of value in bilateral mastoiditis as it shows which side is thrombosed.

Treatment—If thrombosis is suspected, a simple mastoidectomy is performed if this has not already been done and the lateral sinus exposed at its sigmoid portion. If investigation confirms the diagnosis, the internal jugular vein should now be ligated and cut between two ligatures. If the vein itself is infected it should be excised even to the jugular bulb. Returning now to the lateral sinus, the latter is incised and the clot removed. If free bleeding is obtained from both ends the wound is merely picked. If bleeding does not occur from the upper end it should be exposed until free bleeding is obtained and then picked, gauze being inserted between the bone and the sinus.

Brain Abscess—Abscesses occur usually in the temporo-sphenoidal lobe or in the cerebellum. (See section on Brain Abscess.)

Otitic Meningitis—There may be diffuse suppurative leptomeningitis, circumscribed suppurative leptomeningitis or serous meningitis. Recently the sulfonamide derivatives have been employed in streptococcal and pneumococcal infections such as lateral sinus thrombosis and meningitis. This subject is treated in the section on suppurative meningitis. Any treatment of this condition if otitic in origin is incomplete unless the focus of infection is first removed. This means a complete simple mastoidectomy with exposure of the dura of both the middle and posterior fossae. Sometime in this way an extradural abscess will be discovered. Some otologists of experience also advocate dural incision. Under this plan with adequate chemotherapy and serotherapy plus frequent or continuous cerebrospinal drainage by lumbar puncture the mortality for otitic meningitis (diffuse suppurative) has been reduced in recent years from nearly 100 per cent to well below 50 per cent.

Petrositis—The structure of the petrous pyramid corresponds to that of the mastoid

process and therefore may be pneumatic diploia, mixed or sclerotic in type. Infection may enter by cellular extension from the middle ear or mastoid cells either posterior superior or inferior to the labyrinth or anteriorly between the cochlea and the internal carotid artery. The pathologic process may be either empyema in a cell or cells or osteomyelitis.

In the presence of middle ear or mastoid infection either acute or chronic the symptoms are pain on the side of the lesion frequently referred to the area supplied by the ophthalmic division of the fifth nerve paralysis of the sixth nerve (the Gradenigo triad) a low continued fever a profuse middle ear discharge and roentgenologic evidence of decalcification of the petrosal.

A simple or radical mastoidectomy, depending on the chronicity of the case will afford satisfactory drainage in many instances. At the time of operation fistulous tracts leading to the pyramid should be carefully sought for and, if found curetted. If these measures fail the petrous pyramid may be attacked directly.

The most satisfactory procedure is some modification of Eggleston's technique. After a simple mastoidectomy has been done the dura is freely exposed by removal with gouge or rongeur of the tegmen mastoideum, the squama and the posterior portion of the zygoma. Ventriculopuncture relieves brain tension so that the brain can be retracted and the anterior and posterior surfaces of the pyramid exposed nearly to the internal auditory meatus. If an extradural abscess is discovered it may be drained or the interior of the pyramid may be opened with a curette.

THE THROAT

Anatomy.—The region commonly known as the throat is bounded anteriorly by the base of the tongue laterally and posteriorly by the pharyngeal walls superiorly by the nasopharyngeal space and inferiorly by the hypopharynx. From a surgical standpoint, this area is important primarily because of the fact that it contains in a more or less symmetrical arrangement definite masses of lymphoid tissue characterized as in other parts of the body by lymph follicles enmeshed in connective tissue and particularly in the throat covered by stratified epithelium which dips down into deep crypts and pockets. This arrangement of lymphoid tissue in the throat known commonly as Waldeyer's ring is distributed as follows. On each side of the base of the tongue are two masses of lymphoid tissue known as the lingual tonsil on each lateral wall lying against the superior constrictor muscles of the pharynx and slung between the palatoglossus and palatopharyngeus muscles (the so-called anterior and posterior pillars) is the largest of these lymphoid elements the faucial tonsil. A median mass of tissue known as the adenoid lies just at the base of the nasal septum and covers the upper half of that portion of the posterior pharyngeal wall which is shut off from view by the soft palate. In addition there are smaller and irregularly shaped and sized masses of lymphoid tissue scattered on the lower posterior pharyngeal wall and on the posterior surface and edges of the palatopharyngeus muscle. These masses of lymphoid tissue are found in all proportions. Their fundamental importance lies in the fact that situated at the very gateway to the upper and lower respiratory tract they constitute one of the most important sources of local infection in the entire body. Bacteria becoming lodged in the depths of the epithelial crypts break through into the deeper structures and by vascular or lymphatic transfer are readily borne to other parts of the body. In addition all varieties of local inflammation are manifested in this lymphatic ring thereby giving rise according to the type of invading micro-organism to a group of specific diseases. These inflammatory manifestations of infection may be acute or chronic and necessitate surgical or medical therapy.

PATHOLOGIC CONDITIONS

Acute Tonsillitis.—Primarily because of its size and complex lymphatic and vascular connections the faucial tonsil is representative of the rest of the ring in its reaction to infection. Hence, so-called acute tonsillitis stands for acute infection with any of the common bacterial invaders in the lingual tonsil the adenoid or the pharyngeal nodules. It is characterized by the cardinal signs of inflammation—redness pain (particularly on swallowing) and fever. All the lymphoid structures present a characteristic appearance exemplified in the faucial tonsil by small punctate white yellow spots scattered

external semicircular canal and the facial nerve which lies just below it and above the oval window. The so-called 'bridge' (the outer half of the inner end of the posterior wall of the bony external auditory canal) is removed converting the middle ear into the antrum and the external auditory canal into one cavity. The so-called facial spur (the posterior bony canal wall) is cautiously leveled down as far as possible without injury to the facial nerve. All granulations and necrotic bone are carefully removed from the antrum attic and middle ear. Great caution must be observed in curetting the latter to avoid injury to the footplate of the stapes for fear of causing acute labyrinthitis and consequent meningitis. To prevent infections of the middle ear by way of the eustachian tube its tympanic end should be curetted to produce closure but injury to the internal carotid artery which lies in close proximity must be avoided. After careful inspection of the whole cavity a plastic procedure is done on the membranous portion of the posterior wall of the external auditory meatus. Sulfathiazole ointment packing is inserted via the canal after the wound has been dusted with one of the sulfonamide powders or the entire cavity may be loosely filled with the powder and only enough gauze packing used to keep the plastic flaps in position. Then the retroauricular incision is sutured. If the lateral sinus lies far forward so that the approach to the antrum is very difficult or impossible by the usual route the Stacle operation which seeks the antrum by way of the external auditory canal must be employed.

The operative results are judged from three standpoints: (1) Secretion. If the whole cavity is ultimately lined with epidermis the cavity will be dry in a considerable percentage of cases; however (as high as 30 per cent) some secretion persists. (2) Hearing. If the impairment of hearing before operation is very great much improvement rarely occurs; sometimes the hearing is even worse after operation. (3) Prevention of intracranial complications. If the operation is properly performed this purpose is usually relieved.

Complications of chronic otitis media usually occur at the time of acute exacerbations but they may develop during acute otitis media without any previous attack.

Lateral Sinus Thrombosis—Involvement of the lateral sinus may appear as a perisinus abscess, phlebitis or actual thrombosis within the lumen.

Symptoms—(1) A sudden high rise in temperature accompanied by a chill and then an abrupt drop to normal or subnormal. (2) Marked leukocytosis especially an increase in the polymorphonuclear leukocytes. (3) Edema over the posterior portion of the mastoid process if the emissary vein

is involved and (4) embolism which often occurs and affects the joints, heart, muscles, lungs or other parts of the body.

Diagnosis—Pneumonia and other causes of pyemia as well as malaria must be excluded. The Tobe-Ayer test is often of value in determining whether or not occlusion is present. It is also of value in bilateral mastoiditis as it shows which side is thrombosed.

Treatment—If thrombosis is suspected a simple mastoidectomy is performed if this has not already been done and the lateral sinus exposed at its sigmoid portion. If investigation confirms the diagnosis the internal jugular vein should now be ligated and cut between two ligatures. If the vein itself is infected it should be excised even to the jugular bulb. Returning now to the lateral sinus the latter is incised and the clot removed. If free bleeding is obtained from both ends the wound is merely packed. If bleeding does not occur from the upper end it should be exposed until free bleeding is obtained and then packed gauze being inserted between the bone and the sinus.

Brain Abscess—Abscesses occur usually in the temporo-sphenoidal lobe or in the cerebellum. (See section on Brain Abscess.)

Otitic Meningitis—There may be diffuse suppurative leptomeningitis, circumscribed suppurative leptomeningitis or serous meningitis. Recently the sulfonamide derivatives have been employed in streptococcal and pneumococcal infections such as lateral sinus thrombosis and meningitis. This subject is treated in the section on suppurative meningitis. Any treatment of this condition if otitic in origin is incomplete unless the focus of infection is first removed. This means a complete simple mastoidectomy with exposure of the dura of both the middle and posterior fossae. Sometimes in this way, an extradural abscess will be discovered. Some otologists of experience also advocate a dural incision. Under this plan with adequate chemotherapy and serotherapy plus frequent or continuous cerebro-spinal drainage by lumbar puncture the mortality for otitic meningitis (diffuse suppurative) has been reduced in recent years from nearly 100 per cent to well below 50 per cent.

Petroitis—The structure of the petrous pyramid corresponds to that of the mastoid

process and therefore may be pneumatic, diploic, mixed or sclerotic in type. Infection may enter by cellular extension from the middle ear or mastoid cells either posterior, superior or inferior to the labyrinth, or anteriorly between the cochlea and the internal carotid artery. The pathologic process may be either empyema in a cell or cells or osteomyelitis.

In the presence of middle ear or mastoid infection, either acute or chronic, the symptoms are pain on the side of the lesion, frequently referred to the area supplied by the ophthalmic division of the fifth nerve, paralysis of the sixth nerve (the Gradenigo triad), a low, continued fever, a profuse middle ear discharge and roentgenologic evidence of decalcification of the petrous.

A simple or radical mastoidectomy, depending on the chronicity of the case will afford satisfactory drainage in many instances. At the time of operation, fistulous tracts leading to the pyramid should be carefully sought for and, if found, curetted. If these measures fail, the petrous pyramid may be attacked directly.

THE THROAT

Anatomy.—The region commonly known as the throat is bounded anteriorly by the base of the tongue, laterally and posteriorly by the pharyngeal walls, superiorly by the nasopharyngeal space and inferiorly by the hypopharynx. From a surgical standpoint this area is important primarily because of the fact that it contains in a more or less symmetrical arrangement definite masses of lymphoid tissue characterized as in other parts of the body by lymph follicles enmeshed in connective tissue and particularly in the throat, covered by stratified epithelium which dips down into deep crypts and pockets. This arrangement of lymphoid tissue in the throat known commonly as Waldeyer's ring is distributed as follows. On each side of the base of the tongue are two masses of lymphoid tissue known as the lingual tonsil, on each lateral wall lying against the superior constrictor muscles of the pharynx and slung between the palatoglossus and palatopharyngeus muscles (the so-called anterior and posterior pillars) is the largest of these lymphoid elements, the faucial tonsil. A median mass of tissue known as the adenoid lies just at the base of the nasal septum and covers the upper half of that portion of the posterior pharyngeal wall which is shut off from view by the soft palate. In addition there are smaller and irregularly shaped and sized masses of lymphoid tissue scattered on the lower posterior pharyngeal wall and on the posterior surface and edges of the palatopharyngeus muscle. These masses of lymphoid tissue are found in all proportions. Their fundamental importance lies in the fact that, situated at the very gateway to the upper and lower respiratory tract, they constitute one of the most important sources of focal infection in the entire body. Bacteria becoming lodged in the depths of the epithelial crypts break through into the deeper structures and by vascular or lymphatic transfer are readily borne to other parts of the body. In addition all varieties of local inflammation are manifested in this lymphatic ring thereby giving rise according to the type of invading micro-organism, to a group of specific diseases. These inflammatory manifestations of infection may be acute or chronic and necessitate surgical or medical therapy.

PATHOLOGIC CONDITIONS

Acute Tonsillitis.—Primarily because of its size and complex lymphatic and vascular connections the faucial tonsil is representative of the rest of the ring in its reaction to infection. Hence, so-called acute tonsillitis stands for acute infection, with any of the common bacterial invaders in the lingual tonsil, the adenoid or the pharyngeal tonsils. It is characterized by the cardinal signs of inflammation—redness, pain (particularly on swallowing) and fever. All the lymphoid structures present a characteristic appearance exemplified in the faucial tonsil by small punctate white-yellow spots scattered

over the mucous membrane surface of the tonsil and representing epithelial crypts filled with desquamated epithelium and bacteria (follicular tonsillitis). The treatment is largely medical including forcing of fluids, rest in bed, free alkalization and the use of some preparation of salicylic acid. Hot saline irrigations are often helpful.

Within the past two years there has been an increasing disposition on the part of many general practitioners to administer some form of chemotherapy particularly sulfadiazine in acute tonsillitis. While the condition is usually self limited chemotherapy is frequently effective in preventing secondary complications especially peritonsillar abscess.

Diphtheria.—In a somewhat similar way the tonsil and also other portions of the ring may become involved in a diphtheritic infection. Due to a specific infection with the diphtheria bacillus and far less common than formerly this disease must still be borne in mind as a possible explanation for the characteristic picture of a grayish white membrane with irregular shape and margin which bleeds freely on removal has a characteristic odor and contains fibrinous meshes and active organisms. The immediate symptoms and treatment are essentially medical rather than surgical. The same is true of Vincent's angina. Here the lesion is a necrosis of the epithelium with a deeper destruction of tissue; there is no true membrane to be removed and the specific spirochete and bacillus in symbiosis make the diagnosis relatively easy.

Septic Sore Throat.—Much more violent in its inflammatory manifestations is the so-called acute streptococcal infection of the throat which is characterized by a general diffuse fiery redness of all the mucosal surfaces not alone of the tonsil but of the adjacent pillars and palatal surfaces as well. There is no true membrane but pseudo-membranous patches may be found on the tonsillar surface. There are high fever and prostration with systemic toxemia which in one specific form is either identical with or similar to scarlet fever.

Since this form of acute inflammation in the throat is often more violent and more likely to manifest systemic symptoms the administration of chemotherapy is much

more rational and appropriate than in the case of simple acute tonsillitis.

Cancer likewise does not spare the epithelial surfaces so obviously presented by the tonsil crypts. The lesions are characterized by ulceration and necrosis and as in other parts of the body are prone to progress unnoticed until beyond surgical help. While radical surgical treatment with complete extirpation of the involved area together with block dissection of the neck has had its advocates today the greater enthusiasm is for treatment with x-ray and radium.

Like any other buccal mucosa, the tonsil is subject to certain diseases which are often found in other parts of the mouth such as tuberculosis, syphilis, leukoplakia, etc. Their local treatment falls rather in the domain of dermatology than surgery.

TONSILLECTOMY

Since Waldeyer's ring is frequently the site of a wide range of pathologic processes laryngologic surgery has developed a procedure for the removal of two masses and frequently a third mass of this tissue—the two faucial tonsils with or without the lingual tonsils depending on their size and degree of involvement and the large central mass or adenoid. The surgical removal of these structures has become without doubt the commonest and most frequently performed operation of modern times. As such it has been productive of an untold amount of benefit to the human race and likewise through popular overenthusiasm and performance by inadequately trained operators the source of great harm and even of tragic fatality.

Indications for Operation.—First among the dependable indications is gross hypertrophy. Not infrequently and especially in children the faucial tonsil will be so large as practically to meet in the midline. This may be so even without previous infection, glandular enlargement or history of any acute inflammation and yet the interference with eating or breathing (in which a similarly hypertrophied adenoid is involved) will make removal of these organs imperative. The classical crises of a child in whom this symptom complex is present is well known together with its effect on the weight, general well being and mentality.

The second classical indication for removal of the tonsils and to a lesser extent the adenoids is the history of previous acute infections particularly of the follicular type. When there has been only one such infection it may be good practice to wait the occurrence of another but certainly evidence of repeated attacks of tonsillitis constitutes a generally accepted indication.

Enlarged cervical glands draining the tonsillar area are accepted as pointing to these organs as the primary source of trouble and hence as warranting their removal. Particularly where these glands show evidence of tuberculosis either on dissection or incision it is likely that the tonsil harbors tuberculosis which should be eradicated.

The recurrence of attacks of otitis media is a well recognized indication for removal of the adenoids. Regarded as promoting the entrance of infection to the eustachian tubes this tissue has been removed from countless children with untold benefits in the matter of arrested and eradicated deafness cessation of acute middle ear infections and prevention of mastoid and cerebral complications.

Beyond this local field lies a vast range of lesser indications which have been accepted or rejected by different operators according to their individual enthusiasm and the results obtained. Recurrent bronchitis and laryngitis repeated head colds nasal sinusitis even pneumonia have all been thought to have been cured or their recurrence prevented by removal of tonsils and adenoids. Still more remote are those general systemic conditions such as rheumatic fever chorea psoriasis nephritis and arthritis which have been enthusiastically treated by tonsillectomy on the ground that they are due to focal tonsillar infection.

Examination—How then shall the conscientious surgeon decide? He must base his opinion on a careful history a careful medical examination to exclude other conditions as a cause of the symptoms and finally and of less importance than either of the others on the local examination. The latter should consist of an inspection of the throat to determine the size and configuration of the tonsil the injection of the pillars and the arrangement of the other lymphoid masses. The existence of cheesy deposits within the

crypts of the tonsil is often suggestive of infection but the presence of fluid pus best seen on evertng the tonsil by pressure on the anterior pillar is far more conclusive evidence of the existence of infection. Attention to the nose the cervical glands and the ears should complete the examination.

Operative Technique—Granted that operation has been recommended how shall it be performed? In children the anesthesia of choice is ether though many competent advocates of the guillotine type of operation employ gas and oxygen alone. The greater relaxation afforded by ether anesthesia and the longer time available for careful checking of bleeding and thorough inspection of the throat make it distinctly preferable. The same is true for adults so far as general anesthesia is concerned. In many parts of the country however particularly the South and the West a large proportion of the tonsillectomies are performed under local anesthesia in adults.

Probably no surgical procedure boasts of greater variety in technique than does tonsillectomy. In general however the various methods group themselves into two main subdivisions: (1) the method of dissection and (2) the guillotine method. In the former the peritonsillar tissues are dissected away from the tonsil by various knives or scissors and the tonsil is enucleated from its bed against the pharyngeal constrictors by passing a cold wire snare about it including its so-called capsule and leaving behind a smooth muscular aponeurosis. In the second method any one of a variety of fenestrated instruments is used through the ring of which the tonsil is pushed and held while a sharp blade is pushed down behind it severing its attachments which are held back by the surrounding ring. Hemostatic blades and various other accessories are in frequent use but the principle of dislocation of the tonsil from its bed and its severance with a blade is common to all of them. The merits claimed for the latter method are rapidity uniformity of the preservation of surrounding tissues and lessened postoperative discomfort. There is however some risk of leaving small tonsillar fragments behind especially at the basal portion which must be removed with the snare as in dissection. In the removal of adenoids there are two

principal schools those who favor the scraping of the mass from the pharyngeal wall with a special curette and those who prefer an instrument which severs the adenoid with a flexible cutting blade and collects it in a box like container into which the end of the knife blade is fitted. By any method the work is blinder than is the case with the tonsil and great care must be taken to assure complete removal yet without inflicting injury on the deeper living tissues and blood vessels.

Like many another widely practiced operation tonsillectomy of necessity comes to be regarded by many somewhat lightly and as having no special risk. The mortality is the lowest of any surgical procedure considering the great number of operations but the occasional fatality in any non urgent and purely elective procedure only emphasizes the more tragically the importance of taking every precaution and of employing constant vigilance particularly in large cases so that nothing shall ever go wrong in this operation. In this light the procedure is not a minor one and should never be regarded as such. In particular should the surgeon be on guard against hemorrhage within the first twelve hours which if unrecognized particularly in a child may have the most dire consequences. It should be checked at once either by suture in the case of the tonsils or by post nasal packing in the case of the adenoid. Secondary or late bleeding is usually of less significance and is far more amenable to simple measures for control.

PERITONSILLAR ABSCESS

In general acute tonsillar infections are self limited and the immediate acute attack subsides without incident. At times however after a period of quiescence during which recovery is apparently progressing there occurs a return of the local pain and inflammation more severe than the original affliction and accompanied by special signs and symptoms. Chief of these is a pronounced difficulty in opening the mouth the pterygoid muscles as a result of inflammatory edema being set so rigidly as to prevent the jaw from opening more than an inch. At the same time there develops a diffuse swelling near the upper pole of the tonsil involving the anterior pillar and half of

the soft palate with a characteristic fiery red and shiny edematous appearance. Fever is usually absent. This condition known as a peritonsillar abscess or quinsy sore throat is rarely seen in children is usually unilateral and is preceded by an attack of acute tonsillitis. It produces intense pain and demands free drainage as soon as there is a definite localization of pus in the loose areolar tissue of the supratonsillar fossa. Until this localization has developed, the patient should be made as comfortable as possible with sedatives external heat and hot throat irrigations since unsuccessful attempts at drainage are worse than none at all and only cause the patient added suffering. As soon as the definite localization of pus is evidenced by an elastic feeling on palpation of the involved region and the appearance of a tense fullness near the supratonsillar fossa surgical drainage is indicated. This is best performed under local anesthesia with topical applications or cocaineization of the sphenopalatine ganglion. A sharp knife is pressed through the top of the anterior pillar or just underneath its edge into the abscess cavity until a trickle of pus is seen to follow its withdrawal. A sharp pointed hemostat is then introduced into this same tract to the center of the abscess and is then forcibly opened enlarging the drainage tract and providing free exit to the pus. This latter procedure is momentarily very painful but the succeeding relief is so rapid and complete as to more than justify it. No special treatment is needed beyond some cleansing gargle or irrigation.

LATERAL PHARYNGEAL ABSCESS

Somewhat similar to and often mistaken for true peritonsillar abscess is an infection of the throat best designated as a paratonsillar or lateral pharyngeal abscess. In these cases there is found a localized collection of pus external to the superior constrictor muscles of the pharynx either lateral to the tonsil or just behind it. If the pus forms posterior to the tonsil there will appear a bulge in the pharyngeal wall, which gradually shows definite fluctuation. As soon as this is present incision and drainage is indicated best carried out even in children without anesthesia. Where the pus forms lateral to the tonsil the removal of the latter may be

the ideal procedure in the approach to incision and drainage the abscess being found to lie directly outside the tonsillar bed. In some instances when the infection is more deep seated and occupies the region known as the pharyngomaxillary fossa in close approximation to the great vessels in the neck, particularly if accompanied by signs and symptoms of general systemic and blood stream infection the approach should be from the outside. A generous incision should be made with dislocation of the submaxillary gland and the tract should be followed above the posterior belly of the digastric muscle toward the styloid process (as advocated by Mohr). This approach will reach almost any collection of pus in the pharyngomaxillary fossa.

RETROPHARYNGEAL ABSCESS

A throat infection of great importance is that known as retropharyngeal abscess. Much more common in infants than in older children and adults this condition arises as a collection of pus behind the posterior pharyngeal wall anterior to the prevertebral fascia. It is rarely directly in the midline but not so far lateral as the true lateral pharyngeal abscess. It is most often due to an infection of a prevertebral lymph node secondary to some minute pharyngeal infection. Rarely it is of tuberculous origin originating as a cold abscess secondary to involvement of the cervical vertebrae. The retropharyngeal abscess varies greatly in the depth of its location. It may be high clearly visible above the base of the tongue or so low down as to be scarcely palpable to the examining finger and hence to constitute almost a retropharyngeal abscess. When it is located high up the symptoms are suggestive of some low grade respiratory obstruction such as is encountered with hypertrophied adenoids. There is a snoring or snuffling type of breathing with some nasal discharge. In addition there is usually a story of some difficulty in swallowing i.e. refusal of food regurgitation or marked dysphagia. More serious than any of these symptoms however is that of increasing dyspnea due in the lower location to pressure against the larynx and upper portion of the trachea. The possibility that such respiratory obstruction in an infant may be

due to retropharyngeal abscess must never be forgotten if an occasional tragedy is to be avoided. For some reason examination of these babies is fraught with considerable risk and the opening of a mouth gag or insertion of a laryngeal speculum has been followed by sudden death possibly from some effect of pressure on the vagus. Roentgen examination will almost always confirm the diagnosis by evidence of a greatly widened space between the trachea or larynx and the cervical spine. Forewarned is forearmed no matter how suggestive the history of intrinsic respiratory obstruction may be the possibility of retropharyngeal abscess must always be kept in mind.

The preferable method of treatment is carried out with the child lying on the table with extended head and elevated shoulders. By reflected light the operator seated on a stool and fixing the child's feet exposes the retropharyngeal wall by elevating the tongue and hence the larynx with an angular tongue depressor much as one would hold a laryngoscope. This provides a constant free airway to the glottis and brings into view the pharyngeal swelling even if it is below the level of the larynx which is always at a higher level and hence safe from aspiration of pus. Under direct illumination a knife is then passed into the abscess its contents slowly aspirated and the wound edges spread apart to afford good drainage. Usually no after treatment is necessary and secondary incision is rarely required.

IFUT COMMANDER LYMAN RICHAARDS

NEOPLASMS OF THE NOSE, PHARYNX AND NASAL SINUSES

BENIGN NEOPLASMS

Nasal Polyps—Nasal mucous polypoid edematous fibroma or myxoid fibroma usually multiple and bilateral is the most common benign nasal tumor and has a great tendency to recur. It is a smooth oval usually pedunculated translucent mass growing from the mucosa over the middle turbinated bone the ostia or the sinuses.

Etiology—Formerly chronic infection was accepted generally as the cause of this growth but recently both clinical and laboratory studies have shown that allergic

sensitivity is the underlying constitutional cause." Kern and Schenck have stated and from personal experience the writer concurs with them that true nasal mucous polyps are rare in patients with nonallergic disease even in the presence of extensive sinus infection.

Pathology—An edematous mucous membrane³ is the chief pathologic finding. Eiliated cells are few or absent. Plasma cells, mononuclear cells and lymphocytes may be found but eosinophils usually are abundant and may be the only cells encountered.

Symptomatology—Nasal obstruction, sneezing, watery or purulent discharge depending on the amount of secondary infection, cough and bronchial asthma are the predominant symptoms.

Diagnosis—The family and personal histories of allergy are of the utmost diagnostic importance. The appearance and situation of the growths, the presence of eosinophils in the blood and nasal secretions, protein sensitivity tests and x-ray examination of the sinuses all aid in establishing the diagnosis.

Treatment—Treatment consists in avoidance of or desensitization for offending allergens, surgical removal of the polyp by snare and forceps and treatment of the accompanying sinusitis.

Other Benign Nasal Tumors—Other benign tumors of the nose include the (1) fibrous polyp which is characterized by hypertrophy of the mucous membrane and is often associated with infection of long standing; (2) fibroma and (3) enchondroma which are treated by surgical removal; (4) angioma usually situated on the septum and treated by cautery or destruction by radium; (5) epithelial papilloma⁴ which is a precancerous lesion and demands thorough surgical removal, cauterization of the base or electrodesiccation; (6) psammoma⁵ or brain sand tumor which probably always originates from the dura and may protrude into the ethmoid area and demands surgical removal; (7) Schwannoma or neurofibromatosis which is due to a proliferation of the cells in the sheath of Schwann; and (8) chordoma⁶ which arises from the cellular remains of the notochord, is of epithelial origin, grows from the sphenoid-occipital region and when removed surgically tends to

recur, is slowly malignant and occasionally metastasizes.

Osteoma—Osteomas⁷ are slow growing benign bony tumors originating from the interior of the frontal sinus, the orbit, the ethmoid, the antrum or the sphenoid. Such growths may involve the frontal and ethmoid sinuses and the orbit. They are not common, less than 300 cases having been reported. By far the greatest number occur in patients who are in the second and third decades of life.

Etiology—A definite history of injury can sometimes be obtained but it is doubtful whether either trauma or infection is an etiologic factor.

Fig. 410—Osteoma of the ethmoid in a boy aged seventeen with encroachment on the right orbit producing exophthalmos, diplopia and loss of vision. Operation was performed with relief of symptoms.

Pathology—These tumors may be irregular, sessile or pedunculated and may be composed of (1) hard, eburnated bone; (2) spongy bone; or (3) a mixture of these two types. Grossly they cannot be distinguished from normal bone.

Symptomatology—Small osteomas within the sinuses may cause no symptoms and are discovered only when an x-ray examination is made for other reasons. The first sign may be an acute sinusitis. Later the symptoms are those resulting from the growth of the tumor—headache, pressure on surrounding nerves or paralysis. If the tumor is situated in the nasal cavity it produces obstruction and external deformity. If it grows into the

orbit it may cause diplopia, proptosis or even loss of vision as a result of pressure. Invasion into the cranial cavity usually produces very severe headache. Osteoma of the frontal sinus may produce vertigo reflexly.

Diagnosis—Headache and deep pain lead the patient to seek relief and roentgen examination reveals the size, origin and structure of the growth. Cysts may be differentiated from osteoma by puncture; mucocele may be differentiated by the thinning of the bone and by the roentgenographic appearance. Syphilitic growths involving the soft tissues or the bone may be mistaken for osteoma but roentgenographic and serologic examinations usually make differentiation possible.

Prognosis—The mortality rate in cases of osteoma without operation has been estimated at 48 per cent.⁸ Complications can arise from encroachment on the cranial cavity or surrounding structures. An osteoma within an acutely inflamed frontal sinus may take on serious aspects. If the tumor is situated around vital parts its removal may be impossible. An osteoma of the sphenoid is generally inoperable because of the danger of injuring the brain, the internal carotid artery or the cavernous sinus. In uncomplicated cases when the osteoma can be removed completely the results are satisfactory and the growth does not recur.

Treatment—An osteoma should be removed as soon as it is discovered even though it is not producing symptoms for the possibility of its rapid growth with invasion of the meninges and other vital structures is always imminent.

Nasopharyngeal Fibroma—Nasopharyngeal fibroma is a rather rare tumor of young adult life which occurs chiefly in males. It may grow from any part of the nasopharynx which contains fibrous tissue. It is rounded and smooth, occasionally lobulated, is covered by mucous membrane, is composed of connective tissue and seldom shows calcification, cartilage or bone. The tumor has an abundant blood supply; the vessels generally are of large size and have thin walls. The usual site of origin is from the peristosteum and the anterior portion of the base of the occipital or sphenoid bone.

Pathology—The growth contains spindle cells, round cells and giant cells and is some-

times difficult to differentiate pathologically from sarcoma.

Symptomatology—Nasal obstruction, muffled voice and pressure against the eustachian tubes are the most prominent symptoms. As in sarcoma pain does not appear until the tumor attains sufficient size to cause pressure on the surrounding nerve trunks. There may be repeated attacks of bleeding from the tumor and if the growth is large pressure may cause spreading of the surrounding bone.

Diagnosis—A diagnosis can be made from posterior rhinoscopy and from the hard consistency of the tumor on palpation.

Treatment—The mortality rate from operation alone has been high because of profuse hemorrhage. Destruction of the tumor by electrocoagulation or radium yields far more satisfactory results.

MALIGNANT NEOPLASMS

Malignant neoplasms of the nasal passages do not produce definite pathognomonic signs and symptoms in their early curable stages. The first signs are those of inflammation and hence malignant tumors may be overlooked unless complete investigations are made on every patient whose symptoms are out of proportion to the apparent disease and who has persistent unilateral epistaxis. All tissues removed at operations on the nose and sinuses should be examined by a competent pathologist who is thoroughly familiar with the histology of nasal tissues and if there is the slightest doubt a biopsy should then be performed. The specimen should always include more than the overlying granulation and inflammatory process and should contain sufficient tissue to enable the pathologist to render a definite opinion.

Often what has been mistaken for a recurring benign polyp has been removed from the nose several times before a tumor of malignant type was recognized. Very frequently what appears to be chronic inflammatory tissue or bleeding granulations is removed or cauterized without histologic examination and the malignant process is recognized only when the growth has attained considerable size or has metastasized widely.

As in cancer elsewhere in the body, com-

plete surgical removal is the ideal treatment but often this is not possible. If an operation is undertaken it should be comprehensive and complete so that all that is necessary can be accomplished at one time. Since the surgical dietum for cancer elsewhere that is removal of the growth with a margin of safety and care not to handle the cancerous tissue cannot apply to this region electrocoagulation, cautery and irradiation must be employed in practically all cases. Many perhaps most of the malignant growths in the nasal passages and pharynx are radiosensitive hence irradiation is advised even in surgical cases and is always employed in inoperable cases.

Fig. 413.—Malignant tumor of the left maxillary sinus in a woman aged forty. Note the destruction of the nasal wall and the protrusion of the growth into the nose and also the destruction of the outer wall of the sinus.

Malignant Tumors of the Sinuses.—A primary malignant tumor may occur in the frontal sinus but the antrum and ethmoid sinuses are far more frequent sites of this disease. Carcinoma of the ethmoid or antrum seldom invades the frontal sinus but frequently spreads to the sphenoid and the orbit, the hard palate, septum and sphenomaxillary fossa.

Pathology.—Of thirty-two malignant tumors of the sinuses observed at the Cleveland Clinic four were sarcoma and twenty-seven carcinoma. This preponderance of carcinomatous lesions agrees with the experience of other observers.⁹⁻¹⁰ The epidermoid carcinoma is the most malignant, the basal cell the least so. The transitional cell medullary type spreads to the glands quickly

while the keratinized tumor does not extend into the surrounding glands. Metastases to the lymph nodes usually are late.

Symptomatology.—In thyroid cancer produces early unilateral epistaxis which is followed promptly by nasal obstruction and later by pain. There may be a sensation of fullness in the antrum or of something in the cheek. Pain is referred to the alveolus or the hard palate on the affected side and increases as the tumor grows.

Diagnosis.—When more than one sinus is involved it is difficult to determine the site of the primary lesion. Nasal hemorrhage and obstruction point to the ethmoid sphenoid region; pain around the teeth points to the antrum. Pain in the alveolus often is attributed to dental infection especially since diseased roots and gums frequently accompany cancer in the vicinity of the mouth and sinuses.

Swelling of the cheek, bulging of the nasointral wall or of the hard palate, exophthalmos and a tumor mass in the nose are paramount signs of a malignant growth in the sinuses. Transillumination yields no decisive evidence but an x-ray examination of the sinuses reveals whether the tumor has destroyed or broken through the bones. Large cysts, mucocoele, fibroma, fibromyxoma and osteoma must be considered in the differentiation but exploration and biopsy establish the diagnosis.

Prognosis.—In our series of cases of carcinoma of the sinuses there has been one twelve year cure, one eight year cure, one six year cure and one two year cure. One of the patients with sarcoma survived for eight years and another for three years. Invasion of the surrounding soft tissues by a malignant growth of the sinuses makes the prognosis unfavorable.

Treatment.—Complete surgical removal or destruction and removal by surgical diathermy followed by radium irradiation leaving the cavity open for inspection for a year or more is the treatment of choice. Operation is possible in any case in which there are no metastases to the brain or the neck. Extreme care should be exercised in the preoperative preparation so that the patient's general condition is improved as much as possible. Tracheostomy may be necessary to facilitate the operation.

The site of the primary incision depends on whether the antrum alone is involved or whether there is invasion of the ethmoid sphenoid region or the orbit. Although the frontal sinus is not often the site of cancer it may be infected because of blocking of the nasofrontal duct and should be cleared out. Hence the incision may be made to include the frontal sinus as well as the antrum and ethmoid. Care should be used to keep the incision away from the eye.

The tumor is removed piecemeal. If the orbit is invaded it may be necessary to sacrifice the eye. The wound is left entirely open. Immediately following the operation radium should be inserted with the hope of destroying any hidden cancer cells. Treatment after operation is prolonged and is limited to removing slough and to the cleansing of the whole area. With the open cavity, radium can always be applied later to any area in which cancer is suspected. The defect in the cheek may be closed by a plastic operation and if the orbit has been sacrificed a prosthesis incorporating a artificial eye and held in place by glasses can be arranged.

Radiation is applied in inoperable cases. The pain may be severe and an alcohol injection or section of the sensory root of the fifth nerve may be necessary to afford the patient some relief.

Malignant Tumors of the Nasopharynx—*Pathology*—Most of the growths which arise in the nasopharynx are carcinomatous but sarcomas also occur. In a group of thirty-two cases in the Cleveland Clinic twenty-three were carcinomas and nine were sarcomas.

Symptomatology—A malignant growth in the nasopharynx may be so small that it causes no local symptoms and the first sign may be extensive metastasis in the cervical lymph nodes. There may be a mucous catarrh of the eustachian tube, unilateral impairment of hearing and as the growth progresses obstructive symptoms and dysphagia. The pain is neuralgic in character.

Prognosis—These growths usually are of a high grade of malignancy and metastasize early and widely. In our series of cases only one patient with carcinoma survived for five years, one with sarcoma survived for eleven years.

Treatment—Surgical removal of the tumors is usually impossible because of their situation; hence both external and interstitial irradiation are employed.

Malignant Tumors of the Tonsil and Pharynx—Malignant tumors of the tonsil and pharynx are rather rare. They may arise from the soft palate, the pillars, the tonsil or the mucous membrane. Their early clinical diagnosis while the disease is confined to the primary area is difficult. It is impossible to distinguish between carcinoma and sarcoma unless a biopsy is made.

Pathology—The gross classification of carcinoma of the tonsil includes papillomatous, non-papillomatous or flat types; the latter may be ulcerative or non-ulcerative. The principal pathologic types of carcinoma of the tonsil are the squamous cell, which is the more common, and the transitional cell. Sarcomas of the tonsil may be lymphosarcomatous or fibroblastic.

Symptomatology—The early symptoms of malignant tumors of the tonsil or pharynx are those of benign hypertrophy, inflammation or peritonsillar abscess. There is a sense of fullness and the pain often simulates neuralgia. The consistency of the growth is hard.

If the hypertrophied tonsil is removed at this stage by the surgeon who does not suspect the presence of cancer, there is a rapid filling in of the tonsillar fossa with return of the growth, which is likely to extend rapidly beyond the tonsillar capsule and invade the regional lymph nodes. Late symptoms are constant clearing of the throat, deep pain, dysphagia, salivation, offensive odor and fixation of the jaw.

Prognosis—These tumors extend rapidly and the transitional cell tumors spread quickly to the regional lymph nodes. Broders places about 60 per cent of these tumors in his classification as of grade IV malignancy.

Treatment is surgical and radiological. Operation yields a high rate of mortality and poor prospects of permanent cure. The majority of sarcomas are extremely radiosensitive and the application of radium and deep x-ray is the treatment of choice. The Coutard method or some modification of it is usually employed and the important points are continuity of treatment and ade-

quate dosage.¹³ Lymphosarcoma usually disappears at the original site rather quickly, only to recur elsewhere.

If operation is performed, the external carotid artery is tied; an incision is made from the symphysis of the jaw to the sternal notch, the hyoid bone is split; the attached muscles are turned back and the digastric muscle and the submaxillary gland are turned upward, and the growth is removed with the electrocautery knife.¹⁴

Malignant Mixed Tumors.—Pathology.—Malignant mixed tumors are derivants of the ducts and acini of the mucous glands in the oral cavity. The writer has seen one such tumor arising from the eustachian tube. These growths usually are not encapsulated and must be classified as of a low grade of malignancy. They tend to recur locally, and if they metastasize, they do so late.

Diagnosis—These tumors can usually be recognized by their firm, smooth surface—a single circumscribed nodule lying under the mucous membrane.

Prognosis—In these cases the prognosis usually is good.

Treatment—If the growth is discovered early and has not invaded important surrounding structures, treatment is surgical, and it usually is possible to remove the tumor completely. Whatever method is used whether removal by operation or destruction, with electrocoagulation or deep roentgen therapy, it is important that the growth be removed completely the first time. Deep therapy reduces the size of the tumor and should be used only if complete surgical removal is impossible.

THE SALIVARY GLANDS AND DUCTS

Salivary Fistula.—Operative incisions and accidental wounds about the face may involve the parotid gland or duct and result in a discharge of saliva through the opening in the skin of the cheek. If the wound is infected, the presence of saliva may at first be disguised by the flow of pus, but as the infection clears up, the diagnosis of salivary fistula will be indicated by the persistent discharge of clear fluid. In the early care of wounds over the region of the parotid duct, the formation of a fistula may be prevented by suturing the severed ends together if they can be found.

A salivary fistula following a wound over the gland itself, in which the duct remains patent, is usually not permanent and will heal spontaneously after a few days or weeks, especially if the salivary flow is reduced by keeping the patient on a liquid

or soft diet and avoiding active mastication. In stubborn cases movement of the lower jaw may be absolutely restricted by wiring the upper and lower teeth together.

Salivary fistula resulting from a loss of continuity of the main parotid duct presents a more difficult problem. Here the mucous lining of the end of the duct proximal to the wound becomes continuous with the skin and little or no saliva enters the mouth through its natural channel. The site of the fistula is significant from the standpoint of treatment according to whether the opening is in front of or behind the anterior border of the masseter muscle. Many methods of operation have been proposed. If the fistula is well in front of the masseter muscle it may be possible to dissect the proximal end of the duct free and implant it into the buccal mucosa so that the saliva will flow into the mouth, the skin margins of the opening being then freshened and sutured. Another plan is that of Kaufmann which consists in passing a small drainage tube through the cheek at the site of the fistula so that its end protrudes into the mouth. The tube is gradually withdrawn from the inside establishing a permanent opening there while the external fistula is allowed to heal.

Where the fistula is over the masseter muscle a new anterior part of the duct may be constructed by making a tube from a flap of buccal mucosa turned back and joined to the remains of the original duct.

PYOGENIC INFLAMMATION OF THE PAROTID GLAND

Blair and Padgett¹ divide the cases into two broad groups: (1) those in which acute inflammation of the gland is the most prominent symptom and (2) those presenting recurrent symptoms of obstruction of the duct with added inflammation of the gland. The obstruction may be caused by swelling of the mucosa, a plug of mucus or a calculus.

Acute Pyogenic Parotitis—Acute pyogenic parotitis usually occurs as a complication of a postoperative condition of an infected wound of an acute infectious disease or as a part of a terminal condition. Most commonly the infection is believed to ascend from the mouth along the lining mucosa of Stensen's duct though it may at times be blood borne. The organism is generally a

staphylococcus but is occasionally a streptococcus. Usually there is a sudden onset with pain and tender swelling in the region of the gland and general symptoms of a severe infection such as chills and high fever. Examination of the orifice of the duct in the mouth usually shows it to be bright red and swollen with cloudy or purulent saliva flowing from it. The swelling is usually unilateral but both glands may be involved. As pus distends the gland the overlying skin becomes red and edematous and fluctuation may be detected. In Blair and Padgett's series of thirty-five cases the death rate was 42.8 per cent.

Treatment—Beginning mild cases are treated by application of heat or cold. When it becomes evident that suppuration is present drainage by incision is imperative unless the condition is a terminal one.* By making a vertical incision at the junction of the cheek with the ear noticeable scarring is avoided. The incision passes down to the capsule of the gland and the skin anterior to it is retracted forward. The capsule is then split horizontally in several places to avoid cutting branches of the facial nerve and openings are made deep in the substance of the gland. The wound is packed wide open with gauze. After healing very little scar remains and usually there are no signs of paralysis of the seventh nerve.

Obstructive Parotitis—Obstructive parotitis is preceded by recurrent swelling usually accompanied by some inflammatory disturbance in the duct. The pain and swelling may be especially pronounced when food is taken. Examination will often reveal a discharge of pus from the duct into the mouth and a stone may be located with a probe or by x-ray examination. Complete obstruction may be followed by abscess formation, the condition then resembling the form already described. In cases belonging to the second group recovery usually follows removal of the obstruction of the duct or drainage of the abscess.

Treatment—For cases of obstruction due to swelling of the lining without stone Hobbs, Snieson and Faust² recommend dilation with graded whalebone filiforms until the duct will allow the entrance of a 22 or 20 gauge needle. Then 2 or 3 cc of saline solution or 2 per cent mercuriochrome is

slowly instilled. The treatment may be repeated daily or at intervals of several days according to the symptoms. If a calculus is present in the duct it should be removed if possible through an incision in the mucosa of the cheek. In chronic inflammation with out stone Blair and Piddgett reported good results by slitting the constricted meatus and suturing its epithelial lining to the mucosa of the cheek. When definite acute abscess forms in the gland drainage by external incision is indicated.

PYOGENIC INFLAMMATION OF THE SUBMAXILLARY GLAND AND DUCT

A similar condition to that observed in the parotid gland may occur—and more frequently—in connection with the submaxillary gland and its duct. The usual cause is obstruction of Wharton's duct by a salivary calculus although cases in which the same symptoms were present but in which it was impossible to locate any stone have been occasionally observed. In a series of seventy-three cases of salivary calculus reported by the writer¹ sixty-six were connected with the submaxillary duct and seven with the parotid, a proportion of almost ten to one.

Symptoms and Diagnosis.—In typical cases the diagnosis should offer no difficulty. There is an acute circumscribed swelling beneath the lower border of the mandible in front of the angle, not connected with the bone and not adherent to the skin. Pain may be severe especially on swallowing. This painful enlargement is particularly noticeable when food is taken. The patient is able to open the mouth. A tender edematous swelling will generally be found in the floor of the mouth along the course of the duct. The outlet of the duct at the side of the frenum of the tongue is usually reddened and pus may be expressed from it. A tender hard nodule—the calculus—may be felt somewhere along the course of the duct by combined intraoral and extraoral palpation. In the milder or subacute recurrent cases the diagnosis may present more difficulty. Here the only indication may be more or less recurrent attacks of circumscribed tender swelling in the submaxillary region. The possibility of calculus should always be thought of under these circumstances and careful inspection will frequently show red-

ness or swelling about the orifice of the suspected duct or pressure may force out a little pus. X-ray examination is valuable in making the diagnosis of submaxillary stone if made with the proper positions. When a calculus is suspected in the anterior two thirds of Wharton's duct a 2½ by 3¼ inch film is placed in the occlusal plane between the upper and lower teeth as far back as possible and the rays are directed from beneath the chin. This bite film will give a clear shadow of any opaque substance in the floor of the mouth. If the stone is far back near the gland a lateral extraoral film may be necessary to show it.

Differential Diagnosis.—Obstructive enlargement of the submaxillary salivary gland is commonly mistaken for a lymphadenitis or a cellulitis due to infection from teeth or tonsils. Careful note of history and symptoms and examination as outlined above with *absence of trismus* will usually exclude a cellulitis of dental origin.

The presence of a subacute swelling in the submaxillary region associated with soreness in the floor of the mouth especially in a person of middle age or beyond may lead one to entertain a suspicion of malignant growth. In a carcinomatous metastasis to submaxillary and cervical lymph nodes the mass in the neck is usually fixed and markedly indurated frequently bound both to the skin and to the bone. When the submaxillary gland is enlarged because of a stone in the duct it is usually more deep-seated, is not fixed to skin or bone and has an elastic feeling. The x-ray examination usually clears up the question.

Treatment.—The treatment of obstruction of Wharton's duct by a calculus consists of removal of the calculus through an incision in the floor of the mouth if possible. When the calculus is far back near the gland it is generally necessary to make a skin incision and remove the submaxillary gland as well as the stone.

RANULA

A ranula is a soft painless semitransparent swelling beneath the mucous membrane of the floor of the mouth containing clear ropv fluid. The exact cause is unknown but it may be due to inflammatory closure of one of the ducts of the sublingual

blind or of one of the smaller mucous glands in this region. It is never associated with a calculus nor with a swelling in the submaxillary region as would be the case if the submaxillary duct were involved. Furthermore, in ranula the submaxillary duct can usually be identified and isolated completely from the cystic swelling.

Ranula usually starts on one side of the median line but as the fluid accumulates the swelling increases so that it may appear to be bilateral. The overlying tissue becomes very thin and finally ruptures discharging a semifluid resembling white of egg. The swelling then subsides and the process repeats itself.

Several methods of treatment of ranula have been suggested including removal of the overlying tissue to create a permanent wide opening but the only way of insuring cure is by complete dissection of the sac.

TUMORS OF THE SALIVARY GLANDS

Mixed Tumor—The tumor which most commonly affects the salivary glands is the so-called mixed tumor which occurs usually in the parotid region but is also occasionally found connected with the submaxillary gland. Mixed tumors may also be found in the palate lip and cheek. The mixed tumor appears as a well defined firm swelling sometimes smooth sometimes nodular in the region of the salivary gland with the skin freely movable over it. It increases slowly in size over a period of years and is painless. If untreated it may reach the size of a grapefruit. These tumors while appearing in the region of the salivary gland or even embedded in it are not really part of the gland but are distinctly encapsulated. Histologically the characteristic cells are difficult to classify but are probably of epithelial origin. In parts there is a definite arrangement of these epithelial cells in the form of acini in others there are large amounts of colloid material. Cartilage and bone formation occurs occasionally. On section into the growth the tissue is found to have a peculiar gelatinous consistency.

Prognosis—These growths are not to be regarded as malignant though local recurrence is common if removal has not been complete. Cure usually follows removal.

Treatment—When small and well encapsulated the tumor should be enucleated.

Removal of large growths in the parotid region may be attended with danger of injury to the facial nerve. Radium and x-ray treatment are not very successful.

Carcinoma—Carcinoma may occur in the parotid gland and produces a hard fixed swelling accompanied by pain. If it is untreated ulceration of the overlying skin may occur. Paralysis of the seventh nerve is a frequent accompaniment. Treatment consists in early removal of the entire gland followed by irradiation.

THE JAWS

INFECTIONS OF THE MAXILLARY BONES

Nearly all cases of infection of the maxillary bones are directly or indirectly of dental origin. However, general diseases such as syphilis and tuberculosis may be etiologic factors even though pyogenic infection from the mouth plays an important role. Poisons such as mercury, arsenic, phosphorus and radium salts cause periostitis and osteomyelitis of the jaw bones either by their direct action or by lowering the resistance of the tissues so that pyogenic bacteria gain entrance through diseased teeth and gums.

Etiology—The commonest causes of periostitis, osteomyelitis and necrosis of the jaw bones are local infections following dental, alveolar abscess, stomatitis or fracture.

Sometimes the pus of a dental alveolar abscess instead of making its exit through a perforation in the bone near its point of origin spreads through the cancellated tissue of the mandible causing osteomyelitis. In other cases the periosteum is stripped off the bone to such an extent as to impair the vitality of a certain portion. The hypodermic injection of a local anesthetic into

acutely inflamed tissues for the extraction of a tooth may carry infection ahead of it thus leading to periostitis and osteomyelitis. Injudicious extraction of a tooth in the very acute stage of periosteitis especially when considerable trauma is entailed frequently is followed by inflammatory bone complications. Periostitis and osteomyelitis generally result in bone necrosis. Cases have been recorded in which the sequestrum comprised the entire mandible. Regeneration of bone after necrosis is much more frequent in the mandible than in the maxilla.

Symptoms.—Inflammatory disease of the jaw bones may be divided clinically into two stages. (1) the acute fulminating stage and (2) the more chronic stage of sequestrum formation. In its earlier stages osteomyelitis is difficult to distinguish from acute dental abscess as severe pain, swelling and fever usually accompany both. In every dental abscess there is necessarily a localized bone infection. If the symptoms persist or involve a more extensive area of the jaw after incision and drainage of the primary abscess the development of osteomyelitis should be suspected. In an advancing case the swelling extends along the bone, the teeth become successively loosened and pus is seen discharging into the mouth around the necks of the teeth. The pus also burrows from the outer surface of the bone toward the skin and if the swelling is not incised will perforate the skin surface forming sinuses. A probe passed through these openings will feel denuded bone. Exposed bone may also be visible through the mouth. After about six or eight weeks sequestra will loosen and in some cases will be thrown off spontaneously. Pathologic fracture may occur. Quite frequently in the mandible however an involucrum of new bone is formed which preserves the continuity of the jaw. X-ray examination affords little information in the acute stages of osteomyelitis before marked disintegration of the bone has occurred. In the stages of necrosis the x-ray picture is valuable in outlining sequestra, new bone formation, pathologic fracture, involvement of teeth, etc.

Treatment.—Adequate drainage should be provided in all infections of the mouth. Any cause that may be manifest such as an abscessed tooth should be removed unless

the case is seen in the acute fulminating stage when the trauma of the tooth extraction might aggravate the infection and open up new channels. When there are indications that pus is present it should be evacuated. This can sometimes be accomplished by an incision within the mouth especially when the upper jaw is involved but in the lower jaw external incision is usually necessary. The incision should be planned so as to give dependent drainage; it should be adequate but not larger than necessary, it should follow the natural lines of the skin and should be so placed that the resulting scar will be concealed as far as possible; it should avoid severing important structures. For example, the incision for drainage of a submaxillary abscess should be made well beneath and parallel to the lower border of the mandible in front of or behind the position of the facial artery according to the place of greatest pointing. Incisions above the lower border of the mandible should be avoided if possible. When it is evident that some necrosis will occur waiting for the separation of sequestra by natural processes brings about far better results than radical removal of diseased bone or injudicious curetting. By providing proper drainage and irrigation and then removing sequestra as they form it is possible to have the lost bone almost completely replaced and to avoid any great deformity and interference with function. On the other hand if the diseased bone is resected before sequestration is complete there is generally great interference with regeneration resulting in unsightly distortion of the free malocclusion of the teeth or non-union of the remaining portions of the bone.

NEOPLASMS OF THE JAWS

A convenient clinical grouping of the more common tumors and conditions resembling tumors about the jaws is the following: (1) epulis, (2) osteoma, (3) benign giant cell tumor, (4) sarcoma, (5) tumors cysts and anomalies of dental origin, (6) metastatic and secondary growths and (7) miscellaneous conditions resembling tumors.

Epulis.—Though this term has been objected to on the ground that it simply means any growth on the gum when applied to a definite clinical entity it serves a useful purpose. The characteristics of epulis are: a cir-

circumscribed growth from the alveolar ridge and gingival margin, around the necks of the teeth, having generally a rather narrow attachment and spreading thence over the gum surface, often hiding the crowns of the teeth and displacing them (Fig 444). This definition would exclude growths away from the gum margin, surface growths, such as papillomas, etc. In the early stages epulis may be essentially a chronic inflammatory growth, due to irritation of food or tartar beneath the gum margin, ill-fitting crowns and fillings, or carious cavities in teeth. Some pathologists claim that histologically, at least, an epulis is not a tumor but should be classed as an infectious granuloma. Clinically and grossly, however, it has many of the

consists of an interlacing network of fibrous tissue with round cell infiltration.

The *fibroangioma* is usually softer, grows more rapidly, is bright red and bleeds more easily than the plain fibroma. In the fibrous connective tissue stroma are seen numerous dilated capillary blood vessels.

The *giant cell epulis* is soft, is characteristically dark red or purplish and may increase rather rapidly in size. Microscopically, beneath the covering mucous membrane, there is seen a stroma of fibrocellular tissue, and scattered throughout are multinucleated giant cells. Small masses of bone and cartilage may be found. These growths were formerly called giant cell sarcomas and, regarded as malignant, gave rise to radical and

Fig 444—*a*, Epulis, *b*, roentgenogram showing dental root cyst connected with the maxillary second incisor

characteristics of a tumor and for this reason it is included in the present classification.

Clinically and pathologically three forms of epulis are recognized. (1) fibroma, (2) fibroangioma and (3) benign giant cell tumor. All three types arise from the dental periosteum about the neck of a tooth.

Fibroma is the most prevalent form. Soft at first, it later appears as a hard nodular mass on the gum surface, usually pushing out from a narrow pedicle between two teeth, sometimes displacing the teeth. The covering mucous membrane may be bright red, although it generally resembles that of the normal gum. Fibromas are nearly always slow in growth. Histologically, there is an outer layer of normal stratified squamous epithelium, while the mass of the growth

mutating operations and unnecessary sacrifice of tissue. It is now known that these growths are not malignant and that they require only local removal. Some pathologists regard the giant cell epulis as a manifestation of osteitis fibrosa.

Treatment of Epulis—The great majority of epulides spring from the alveolodental periosteum about the necks of the teeth, and in order to avoid recurrence it is necessary to remove the growth down to the responsible dental periosteum. This usually means that the tooth nearest the growth or perhaps two teeth must be removed. The growth often comes away in extraction attached to the neck of a tooth. Destruction of the growth by radium is not advised, because an entirely unnecessary slow healing

with painful ulceration results probably with exposure and necrosis of bone.

Osteoma.—Osteoma is found more commonly in connection with the maxilla than with the mandible. It forms a dense painless circumscribed enlargement, slow in growth, pushing out from the surface of the bone. The dense character clinically and radiologically distinguishes it from a cyst or sarcoma. The diffuse character of many of these growths makes complete removal difficult or impossible, but often good results are obtained by chiseling away enough of the excess bone to form a normal contour and repeating the process if necessary.

Benign Giant Cell Tumor.—A benign giant cell tumor may arise from the interior of the bone, causing expansion of the cortical plate. If the cortical plate or the alveolar margin becomes perforated by the tumor, the mass will have the typical purplish color seen in the epulis type. Otherwise absolute differentiation from true sarcoma may not be possible before operation. On incision the tissue is dark red as contrasted with the pale gray of the more malignant sarcoma. It is now established that the benign giant cell tumor of bone is a definite stage of osteitis fibrosa cystica. It usually responds well to enucleation and curettage of the mass without encroaching extensively into the surrounding healthy bone.

Sarcomas.—Sarcomas of various types involve the maxilla just as they do other bones. The endosteal form appears to be the most common, causing a painless expansion of the bone at first slow but later progressing more rapidly. In the upper jaw, the maxillary sinus may be invaded with later involvement of the nasal fossa and other sinuses. The x-ray picture is important in distinguishing sarcoma of the jaw from cysts and tumors of dental origin. Benign giant cell tumors and other growths. Sarcoma shows in the x-ray film a peculiar honey-combed appearance with irregular outline. Sarcoma may affect persons at any age. Metastasis occurs through the blood stream and the lungs usually show the first signs of secondary involvement. In many of the slow growing sarcomas of the jaws, metastases do not occur until late and the prognosis is correspondingly favorable.

Combined treatment by radical surgery

roentgen ray and radium is regarded as giving the best hope for cure.

Tumors, Cysts and Anomalies of Dental Origin.—A full discussion of these would require more space than can be afforded here. This group comprises what are often classed together under the term odontoma, though the writer prefers not to use this term because some of the conditions are not tumors at all but are mere calcified abnormal masses of tooth structure.

The first heading to be considered is that of *dentocystic tumors* of which there are three forms: (a) adamantinoma or ameloblastoma, (b) dentigerous or follicular cyst and (c) dental root cyst or radicular cyst.

a. Adamantinoma or Ameloblastoma.—The adamantinoma is the least common of the three forms of dentocystic tumor. It is believed to be due to aberrant growth of the ameloblasts or enamel forming cells of the tooth germ, although there is never any calcified enamel in the tumor. The portion of the jaw involved usually the molar region of the mandible but not necessarily so is distended containing a lobular mass within a bone cavity or there may be several cavities divided by fibrous or bony septums. In the earlier stages the growth may consist largely of solid tissue but numerous cysts are formed later which may finally coalesce into one or two large cysts filled with a viscid yellowish or brownish fluid. Histologically there are nests of columnar and cuboidal epithelium corresponding to ameloblasts surrounding less dense areas with compressed cell bodies resembling the stellate reticulum of the enamel organ. These epithelial areas are surrounded by a supporting connective tissue containing blood vessels. Accumulation of fluid in the cysts may compress the lining epithelium until it becomes squamous. The surrounding bone may be gradually absorbed the tumor cells then breaking through and invading the surrounding soft tissues. Metastases however are practically unknown, only two undoubted cases having been recorded (by Simmons³). In general it may be said that the tumor is to be regarded as benign. It may be found at any age. McFarland and Patterson⁴ have reviewed 100 cases reported in the literature.

Symptoms and Diagnosis.—The patient

resents a painless swelling usually in the molar region of the mandible which has been slowly increasing in size. The jaw is found to be expanded the outer plate being more affected than the inner. When the tumor has broken through the bone it may present a lobulated surface and an elastic feeling on pressure. If an opening into a cystic cavity exists a fluid discharge is seen that is usually viscid and brownish. Infection may occur and obscure the nature of the tumor by showing symptoms of osteomyelitis. The diagnosis from purely inflammatory conditions and from other tumors and cysts can usually be completed by the x-ray picture which shows a cavity in the bone divided by fine bony trabeculae into numerous compartments. Sometimes in the more solid form histologic examination is necessary in order to differentiate the growth from sarcoma.

Treatment—In early cases in which the tumor is small and surrounded by well defined bony walls it is sometimes possible to obtain a cure by enucleation and curettage made from within the mouth followed by implantation of radium. If the tumor is large with irregular extensions into the surrounding bone or perforation into the soft tissues complete resection should be the initial treatment. Of sixteen patients treated by the writer, four are believed to be well after conservative enucleation repeated several times in one case. Two patients are apparently well after a second conservative operation followed by implantation of radium. In four cases complete resection with loss of continuity of the mandible was the initial treatment with complete cure. Six patients after conservative operations have finally come to radical resection with apparent cure.

b Dentigerous Cyst—The dentigerous cyst takes its name from the fact that it bears a tooth and forms a hollow swelling usually filled with clear straw colored fluid and having a partially or fully developed tooth attached by its root portion to the wall of the cyst with the crown projecting into the cavity. There is a lining membrane the inner layer of which is of epithelium derived from cells of the enamel organ. These cysts are usually first noticed about the period of eruption nearly always in con-

nection with the permanent teeth. Any tooth may be involved most commonly the canine and then the mandibular third molar.

Symptoms and Diagnosis—There is a gradually increasing swelling of the jaw bone usually involving the outer plate especially. Later the bone is thinned giving the characteristic parchment or celluloid feeling. The absence of a tooth from the series is a point of great significance. Suppuration may occur. The x-ray picture shows a clear area indicating absence of bone with well defined margins continuing the unerupted tooth.

Treatment—The treatment consists in complete removal of the cyst capsule through an incision in the gum together with extraction of the unerupted tooth. The bone cavity soon fills in by granulation.

c Dental Root Cyst or Radicular Cyst—The dental root cyst is by far the most common form of cyst which develops about the jaws. It nearly always occurs as a sequel to chronic inflammation about the root apex of a tooth as a result of infection following death of the dental pulp. Cysts of this type therefore are most commonly found in adults and in connection with the roots of pulpless teeth. The responsible tooth may have been removed several years previously yet the cyst may continue to grow in the edentulous part of the jaw. The epithelial lining of the cyst is believed by most writers to be derived from the paradental epithelial cell rests of Malassez which are remnants of the cells of the outer layer of the enamel organ persisting normally in the adult dental periosteum. The wall of the fully developed cyst is made up of a dense fibrous capsule lined generally with several layers of squamous or cuboidal epithelial cells. The material in the cyst cavity may be the consistency of butter or it may be a clear straw colored fluid. Secondary infection may convert the contents into pus. These cysts vary in size from that of a small pea to that of a hen's egg. In the maxilla they may encroach on the maxillary sinus or the nasal fossa but they rarely break into these cavities. By extension a cyst may gradually involve the roots of adjacent teeth causing secondary pulp devitalization.

Symptoms and Diagnosis—Small cysts may cause no symptoms whatever the diag-

nosis being made by roentgen ray examination of the apical region of a pulpless tooth. This will reveal a clearly outlined area with sharply defined margins. Larger cysts cause a bulging of the bone about the apex of a pulpless tooth usually labially or buccally or in a location from which a tooth has been lost. The maxillary second incisor is the most frequent seat of development. If rupture into the mouth has occurred there will be a discharge of clear fluid or pus from time to time. There is usually no pain. Cysts that have not discharged fluid must be carefully differentiated from sarcomatous or other solid tumors. Close examination of the roentgenogram will usually make the distinction. In case of doubt needle puncture under aseptic precautions will establish the diagnosis. The x-ray shadow of the cyst may overlap the shadow of the roots of adjacent teeth. Here it is important to test these teeth for pulp vitality. If they are devitalized the success of treatment of the cyst may be interfered with by persistent infection from these teeth. On the other hand if pulps are found to be vital needless sacrifice of sound teeth will be avoided.

Treatment—The practice of simply making an incision into the swelling to provide drainage is to be condemned. This never gives permanent relief and usually introduces infection into a previously sterile region and by the formation of adhesions of the overlying mucous membrane renders radical operation more difficult. The responsible tooth if still present usually must be extracted and any secondarily involved teeth should be removed at the same time. The cyst itself should be treated by shelling out the entire epithelial lining and allowing the bone cavity to fill in by granulation. Small bone cavities may be allowed to fill with aseptic blood clot and may be closed over by suture of the gum flap.

Calcified Dental Anomalies—These are masses of calcified dental tissue usually replacing a normal tooth which consist of a disordered conglomeration of enamel dentine and cementum and sometimes masses resembling misshapen teeth. The mass may be unerupted or erupted. These growths may be discovered at any age and are frequently not recognized until supervening infection causes symptoms of osteomyelitis when the

hard masses are often mistaken for necrosed bone. They may be found in either jaw but more often in the lower and generally in the molar region. The x-ray picture will always reveal the nature of the condition. If a fistula is present and a probe is passed the hard dense character of the tissue is felt to be quite distinct from that of bone.

Treatment—If acute symptoms of infection are present with swelling redness and edema of the tissues of the face and suppuration from the bone early treatment should consist in incision and drainage. After the acute symptoms have subsided the growth should be removed usually from within the mouth after some of the surrounding bone has been cut away sufficiently to liberate the mass.

Metastatic and Secondary Growths—Carcinoma—When carcinoma involves the jaw bones it is usually a direct extension from a primary growth of the oral mucous membrane. Occasionally, it may occur as a true metastasis from cancer of the breast or some other primary source just as other bones of the body are affected in this way.

Thyroid tumors both clinically benign and malignant occasionally metastasize to bone among them the jaw bones. The writer has reported a case of metastasis to the mandible of an apparently benign adenoma of the thyroid which had been removed almost eight years previously.³ In the presence of an otherwise unexplained swelling bearing the characteristics of a tumor or cyst of the mandible the possibility of a metastatic growth should be considered.

Miscellaneous Group of Conditions Resembling Tumors—Torus palatinus an exostosis in the region of the median palatine suture of the maxilla presents an oval usually smooth but sometimes nodular hard swelling in the roof of the mouth. To the uninitiated this may be mistaken for an osteosarcoma. The torus palatinus is found normally as a developmental condition in a considerable percentage of persons; it undergoes no changes in size over a period of many years and causes no pain. Most persons are unaware of the presence of the growth. It demands surgical treatment only when the overlying soft tissues become irritated by rubbing or when the swelling interferes with the proper fitting of an artificial

denture. In such cases it can be removed with a chisel after the overlying mucoperiosteum has been dissected back.

Similar excrescences or *exostoses* are frequently found beneath the gum on the buccal aspect of the mandible in the premolar regions and also around the tuberosities of the maxilla. They are not progressive in growth usually give rise to no symptoms and require removal with a chisel only when they interfere with an artificial denture.

Osteitis fibrosa cystica may occur in the jaw bones especially the mandible producing localized or generalized areas of decalcification alternating with increased density. The diagnosis is established definitely on finding clinical and roentgenologic evidence of similar conditions in other bones and a disturbed calcium metabolism. The treatment is that of the general condition removal of the parathyroid tumor if found and symptomatic local treatment.

Osteitis deformans or Paget's disease is occasionally seen in the upper jaw where its manifestation is termed *leontiasis ossea*. In the maxilla a hard smooth swelling covered by normal gum tissue is seen in the region of the molar and premolar teeth. Later the swelling may be seen externally giving rise to the characteristic leonine features. The x ray plate usually reveals consolidation of the facial bones and sinuses with a peculiar thickening and mottling of the cranial bones. The etiology and the cure are unknown.

- 4 Lymphangioma
- 5 Hemangioma

MIDLINE AND LATERAL CYSTS AND FISTULAS

Incomplete or faulty development of the cephalic portion of the human embryo is believed to result in a variety of anomalies which become evident in childhood or adult life in the region of the neck. These anomalies may take the form of cysts, fistulas and sinuses or solid cell rests. They may be situated in or near the midline or may be lateral, and they may be found anywhere between the mandible and the sternum. These anomalies have been of great interest for over a century and hundreds of contributors have added to our knowledge of them. Attempts at classification have been anatomic, pathologic, embryologic and regional. None has been completely satisfactory, and efforts to simplify the subject have generally made it more confusing. The clinical recognition of these anomalies is generally not difficult and the treatment is fairly well standardized. The pathogenesis of the different varieties, however, is on less firm ground.

Embryology.*—During the last half of the third week of intrauterine life the human embryo shows more clearly than at any other period a series of five parallel bars or visceral arches (branchial arches) obliquely placed on each side of the cephalic portion in the region destined to become the upper part of the neck. These arches are separated from each other on the external surface by grooves termed visceral furrows (branchial clefts) and on the internal surface by evaginations called pharyngeal pouches. Normally the intervening "closing membrane" between each groove and pouch does not rupture, so there is no communication between the visceral furrows and the pharyngeal pouches. From the first arch are developed the upper and lower jaw, the malleus and incus from the second, the lesser cornu of the hyoid, the styloid process and part of the stapes from the third, the body and greater cornu of the hyoid from the fourth, the cuneiform cartilages and most of the thyroid cartilage, and from the fifth part of the thyroid cartilage and the corniculate arytenoid and cricoid cartilages. The first visceral (branchial) furrow or hyomandibular cleft obliterates except at its dorsal part which becomes the external auditory meatus. The remaining furrows disappear. Internally the first pharyngeal pouch gives rise to the eustachian tube and the tympanic cavity; the second forms no permanent organ unless a part is retained as the tonsillar and supra-tonsillar sinus; the third by entodermal outgrowth forms the thymus and the inferior parathyroids; and the fourth the superior parathyroids. The tympanic membrane represents the dividing membrane between the first pharyngeal pouch and the first branchial cleft. Normally the arches become joined together anteriorly, that is on the ventral surface of the embryo. The first and second arches grow more rapidly than the others and overlap them, forming an external groove called the cervical sinus or precervical sinus of Ill.

The thymus gland develops from two stalk-like diverticula which originate during the sixth week from the third and fourth pharyngeal (branchial) pouches. These diverticula grow caudad in the region destined to become the neck and fuse distally to become the thymic gland. During the few days in which these diverticula are patent they are sometimes referred to as the embryonic thymic duct. Normally they are obliterated by the seventh week.

The thyroid gland develops from an outpocketing from that portion of the floor of the pharynx whose location in later life is marked by the foramen cecum on the posterior portion of the roof of the tongue. This epithelial evagination is transformed into a stalked vesicle by the time the embryo has reached a length of 2.5 mm. This vesicle or diverticulum grows down.

*The writer gratefully acknowledges the criticism of this section on embryology by Dr. L. B. Arcey, R. L. Rea, Professor of Anatomy, Northwestern University Medical School.

ward and backward from its point of origin as a tubular duct (thyroglossal duct) which bifurcates at its distal port on to form the thyroïd lobes. During its transitory existence the duct proper passes through or adjacent to a area which at a later time becomes the hyoid bone. Its distal end corresponds to the region which later becomes the pyramidal lobe of the thyroïd. This epithelial lined duct usually atrophies during the sixth week of fetal life. Remnants of an epithelial cord persist for a short time. The pyramidal glands are epithelial bodies arising from the posterior half of the third and fourth pharyngeal pouches.

Etiology—Deviation from the normal development just described may occur in a wide variety of ways. While definite proof is lacking the following theories are the most plausible. Incomplete union of the first two branchial arches in the midline may cause the formation of a midline *sublingual inclusion cyst*. If the failure of union is external the cyst will be epidermally lined (*dermoid*); if the failure of union is internal the cyst will be lined with mucous membrane. Faulty obliteration of the first and second branchial (ectodermal) furrows so that they close only at the external surface may result in inclusion cysts. The second cleft is the offender twenty times more frequently than the first and the results are epithelium lined cysts in the submaxillary, sublingual and submental regions. If the pharyngeal pouch fails to unite completely a pharyngeal diverticulum may develop or if it unites on the pharyngeal surface only a mucous membrane lined inclusion cyst may develop. The ultimate location of these cysts may be the same as those of external origin. The lining of the cysts is generally either ectodermal or endodermal. The probability that it includes both germ layers is small since the branchial furrows and pharyngeal pouches rarely communicate but are separated by a mesial plate. Failure or complete obliteration of the embryonic thyroglossal duct may leave (a) *midline cysts (thyroglossal cysts)* occurring anywhere on the pathway from the foramen cecum through or past the hyoid bone to the pyramidal lobe of the thyroïd; (b) *midline fistulas or sinuses (thyroglossal fistulas)* which may open internally or externally and end blindly or actually may be continuous from the skin of the neck to the foramen cecum or (c) *rests of thyroid tissue* anywhere along the temporary thyroglossal

pathway (Fig. 445). Failure of obliteration of the first and second clefts or possibly of the thymic evagination from the third pharyngeal pouch (embryonic thymic duct) may give rise to inclusion cysts in the lateral portion of the neck which occasionally may be moved toward the midline by growth or a fistula may form a communication from the pharynx near the tonsil to the skin of the lateral portion of the neck. The existence of this complete fistula presupposes the breaking through of the embryonic membrane separating the pouch from the furrow and may come about through an embryonic perforation or a postnatal infectious process. If the external opening is below the hyoid bone some writers think that the embryonic

Fig. 445.—Diagram showing course and relations of the embryonic thyroglossal duct. Fistulas, cysts or thyroïd remnants may involve any portion of this tract.

thymic duct is concerned it is possible that in these cases the transitory lateral thyroid tissues or the cervical sinus may play a role. The parathyroids may be concerned in the formation of lateral cysts. Other congenital anomalies are the congenital fistulas of the ear auricular appendages and congenital skin growths on the side of the neck. A congenital fistula of the neck communicating with the middle ear has been reported (Druss and Allen).

Symptomatology and Pathology—The median anomalies particularly the thyroglossal variety are more common than the lateral ones moreover they are more common in women than in men and appear more frequently in the first two decades than later

in life. The cysts may become apparent at a very early age but more commonly in early adult life as rounded fluctuant swellings at the base of the tongue beneath the tongue in the midline of the neck below the hyoid bone in the subaural and submaxillary regions or in the upper lateral portions of the neck. The growth of the cysts may be interrupted by periods of quiescence. The cysts may rupture spontaneously, generally externally; they may be incised by the surgeon under an erroneous diagnosis or they may become infected hematogenously and require opening. Once the cyst has ruptured a non-healing sinus develops which becomes secondarily infected. Such a sinus may open internally into the pharynx but also externally on the skin of the neck. Occasionally a complete fistula will exist between the pharynx and the skin of the neck. The external opening may appear years after birth and is generally just anterior to the sternomastoid muscle at any level but most commonly in the lower third of the neck. In the complete fistula food may work its way from the mouth through the fistula and be discharged on the surface of the neck. A case of bilateral complete fistulas has been reported. A purulent discharge may occur externally or internally and may vary in amount at different times. These sinuses can act as foci of infection and be a detriment to the general health. When the cysts are large they may become objectionable because of their pressure on adjacent structures or because of their appearance. They may be the source of a carcinoma. The thyroid rests may become important functionally if the normally situated thyroid is underdeveloped.

Histologically the lining of the cyst or fistula may be a derivative of the ectoderm or the endoderm but both embryonic layers are occasionally thought to be present in the same cyst or fistula. In the latter event we must believe that an embryonic perforation existed between the pharyngeal pouch and the branchial cleft. The contents of the cysts vary from clear serum to thick sebaceous material according to the character of the wall. The contents of the cysts and the discharge from the fistulas may be mucoid or purulent.

Diagnosis—All fluctuant cystic swellings of the cervical region may be regarded as possible developmental anomalies. When

they are inflamed and filled with pus their cystic character may be difficult to recognize. The abscess may rupture internally and burrow along the fascial planes of the neck. The embryonic cysts may be distinguished from sebaceous cysts in that the latter are attached to the skin and are superficial to the muscles. Lipomas are softer and generally present the *signe de peau d'orange*. Softened tuberculous lymph nodes or inflammatory adenitis may present considerable diagnostic difficulty. Tubercle bacilli have been found in branchial cysts. Branchiogenic carcinoma may be difficult to distinguish from metastatic carcinoma of the lymph nodes. Cystic hygromas are situated lower on the neck generally just above the clavicle.

The diagnosis of fistula may be facilitated by roentgenography after the injection of substances opaque to the x-ray (such as lipiodol) diluted half and half in liquid paraffin with closure by purse string suture after injection (Bailey) or by the external injection of bitter substances to see if they may be tasted or of methylene blue to see if it appears in the throat. Traction on the skin may demonstrate the cord like prolongation of the fistula. The rising of the fistula with deglutition is said to signify that the fistula is complete. Cysts may be aspirated and injected with substances opaque to the x-ray but they should be reaspirated afterward. Branchiogenic cysts may be found in the parotid gland. Aspirated contents of a branchiogenic cyst may show cholesterol crystals. If there is a swelling at the base of the tongue it should be remembered that a cyst is thin walled and light colored whereas aberrant thyroid tissue is solid and dark red. When cervical cysts attain adequate size there may be symptoms of difficulty in phonation, deglutition or respiration.

Treatment—The treatment of cervical cysts and particularly fistulas by the injection of sclerosing agents although long tried has practically been abandoned. Radical extirpation of the cyst or fistula is regarded by most surgeons as the only method of treatment which offers a chance of certain cure. This at times may be a formidable operation and should be undertaken only in a hospital operating room. The incision should be transverse in the case of a midline fistula and oblique and parallel to the skin creases

in the lateral ones. Builey uses two transverse incisions, one above the other in lateral fistulas. Injection of the fistula with molten paraffin or methyloae blue will aid in the excision. Where a thyroglossal fistula passes through the hyoid or is intimately connected with it about $\frac{1}{4}$ inch of the bone should be removed and the cut ends approximated. Above the hyoid bone no attempt is made to isolate the tract but the duct and tissues around it are coiled out through the muscles of the tongue to the foramen caecum.

Fig. 446.—Shows excision of fistula tract and its relations. Clamp on end of fistula should be used to close the tract to prevent escape of fistula contents. Multiple transverse incisions are preferable (Holman).

(Sistrunk) The tissues for $\frac{1}{4}$ inch around a lateral fistula should be removed and the wound should be drained (Fig. 446). The pharyngeal end of a complete fistula may be inverted into the pharynx and the fistulous tract closed by suture. Where access to the cyst is difficult the sternomastoid muscle may be divided. Preliminary aspiration is thought by some to facilitate excision of a cyst. In some of the cysts which are lined by oncous membrane the cyst wall may be very friable and difficult to remove. If such

wounds are packed with gauze the cyst wall may come out when the packing is removed. Pemberton followed 281 of 293 patients on whom operations for cysts, sinuses and fistulas of the thyroglossal duct had been performed and found only 4 recurrences.

CYSTIC HYGROMA

(*Hygroma Cysticum Colli Cystic Lymphangioma*)

Anomalous development of the lymphatic system is probably the origin of the lymph cysts of the neck in infants and young children. At least part of the lymphatic system begins in two large jugular sacs situated on each side in the region of the junction of the internal jugular and subclavian veins. From this source lymphatics grow distally by budding. The careful studies by Goetsch indicate that cervical hygroma originates from sequestrations derived from the primitive jugular lymphatic sacs. These lymphatic rests retain their embryonic power of irregular growth and therefore may reach almost unlimited size. Although benign these tumors may invade and destroy adjacent muscles or other tissues. They are multilocular and the thin walled cavities are lined with endothelium similar to that found in lymphatic spaces. These cysts may become secondarily infected.

Cystic hygroma is uncommon. Half the cases are noticed at birth and 90 per cent by the end of the second year (Gross and Goeringer). However cystic hygromas may appear in adult life. They are generally found in the neck at the lateral border of the sternomastoid just above the clavicle. They may grow between the clavicle and ribs down into the axilla, up the neck or into the mediastinum and displace adjacent structures by their growth. The cystic hygroma is soft, elastic and painless. Though usually symptomless advanced hygroma may cause difficulty by pressure on the trachea, pharynx or nerve plexuses.

Helpful in the diagnosis is the procedure of Duff. He aspirates about 20 cc of the contents and notes its character. Without removing the aspirating needle he injects an amount of 15 per cent solution of sodium iodide equal to the quantity of fluid aspirated. A roentgenogram of the region is made at once and the resultant film gives an

accurate picture of the ramifications of the hygroma and is a help to surgical excision. In the differential diagnosis lipomas, brain cysts, lymphangiomas and aberrant thyroid tissue must be considered.

The treatment of choice is surgical excision. This may be facilitated by preoperative treatment with radium which is said to make the cysts smaller and in at least one case has effected a cure. The operation is both dangerous and difficult because of the proximity to the great vessels and important nerves and because of the difficulty in removing all the lining of the cyst. The task is a particularly hard one when the cyst extends into the thorax. Gross and Goeringer found no recurrence after surgical excision in 22 cases followed one to thirteen years. Good results were obtained by Watson and McCarthy in 4 of 7 cases by aspiration and injection of 1 to 3 cc of 5 per cent sodium morrhuate solution. This method may be hazardous however because of the danger of introducing the sclerosing solution into the general lymphatic system. X-ray and radium should first be tried in the more difficult cases. In 4 of 7 cases in which x-ray treatment was employed Hodges, Snead and Berger obtained excellent results.

LYMPHANGIOMAS OF THE NECK

Lymphangiomas of the neck are probably congenital and are thought to be neoplastic structures arising from the early capillary lymphatics. In the *simple type* the involved lymphatic vessels are similar to their normal neighbors and the tumor appears on the face or neck as a low partly compressible swelling. In the *cavernous type* there are large endothelium lined lymph spaces with increased fibrous stroma; the tumor is firmer and may involve the skin alone. In the *cystic type* there is an accumulation of vesicle like cysts and the tumors which are generally larger are found on the neck, upper chest and axilla.

Lymphangioma is generally a disease of infancy or childhood and the chief symptom is swelling. The treatment in the majority of cases according to Semken is by irradiation. The firmer cavernous type of tumor may be excised but the excision may be very difficult if the lymphangioma has developed ramifying processes.

HEMANGIOMA

(Angioma)

The term *angioma* is applied to a lesion characterized by a new growth of the blood vessels. In *telangiectasis* on the contrary there is merely a dilatation of pre-existing vessels. The commonest type of angioma is the *nevus vasculosus* or capillary nevus. It begins at birth or shortly after and varies in color from red to purple. It may occur on the neck as well as other portions of the body. The *port wine stain* (birthmark, *nevus flammeus*) is less common. It is red, violet and may cover large irregular non-elevated areas of skin. The *cavernous angioma* is a lobulated bluish mass which may be superficial or deep seated and even invasive in character. Application of carbon dioxide snow is a satisfactory treatment for the vascular nevus although some require x-ray or radium treatment. There is no satisfactory treatment of port wine stains. The *angioma cavernosum* may be treated with radium. According to Watson and McCarthy the treatment of choice for hemangioma at the Memorial Hospital, New York (with the exception of superficial capillary lesions and large inaccessible tumors) is injection with 5 per cent sodium morrhuate solution.

BLOOD CYSTS

Blood cysts may be either true or false. The former are thought to be due to embryonic arrested development, simple venectasia or isolated varices which are gradually shut off from the parent vessel. They may or may not communicate with the vein. The false blood cyst may develop from a hemangioma. The diagnosis generally is not difficult. The treatment is excision through a wide incision and careful attention to hemostasis. (See section on Blood Cysts.)

WOUNDS OF THE NECK

Fractures, dislocations and injuries of the spinal cord are not considered in this section except to state that the cord may be affected by a penetrating wound between vertebral arches from the posterolateral region of the neck.

Anatomy and Pathology.—The covering of the neck in its anterior and lateral parts consists of skin, subcutaneous tissue, platysma and a superficial layer of deep fascia. Beneath this layer of deep fascia the fascia forms the carotid sheath and the compartments which envelop the viscera. These open freely below into the mediastinum. Exudate under pressure thus tends to spread downward either before or after infection has become advanced in the neck itself. The neck is tightly packed with numerous lymphatics, blood vessels, nerves, viscera and muscles. The vessels are large and the many nerves important. Some of the neck viscera are hollow, and if they are perforated, they predispose to infection of the surrounding structures and tissues and lose their normal

functions. The proximity of the mouth, pharynx, esophagus, larynx and trachea adds to the seriousness of neck injuries because of the danger of infection and loss of function. Injury may cause aspiration into the bronchi of blood, secretions and exudate, resulting in pneumonitis and lung abscess. Hemorrhage is the most common and the most serious feature of wounds of the neck. Next in importance to control of hemorrhage is the prevention of infection while the hemorrhage is being controlled. Infection from without is serious, but infection from an open viscus doubly complicates the situation. The profusion of lymph vessels in the neck pours lymph into the open spaces affording an added culture medium.

Injuries of the nerves in the neck are rarely vital, yet paralysis of the laryngeal nerves may weigh heavily against a patient struggling with respiratory embarrassment with its attendant aphonia. The most serious effect of injury of the vagus is paralysis of the recurrent laryngeal nerve. Stab wounds in the supraclavicular region and forcible depression of the shoulder may result in permanent damage to the brachial plexus by severance or by stretching. Injury to the solid viscera is rarely important except that the thyroid gland may bleed profusely. A salivary fistula usually heals spontaneously. The parathyroid glands are rarely injured. Injury to the thoracic duct is uncommon, being more frequent in surgical dissections than in accidental wounds. Its large tributaries are cut more often than the duct itself. After days or weeks of leakage, the wound usually closes. The leakage is clear or milky, depending on food ingestion. Fat foods should be avoided.

Etiology.—It is probable that more accidents to the neck occur during operations than in ordinary life, but in the former the hazard of infection is less. The commonest surgical accidents are hemorrhage from large veins and damage to nerves, the nerves most commonly damaged being the accessory and the recurrent laryngeal nerves. Some writers emphasize the danger of air embolism, but in his experience with many large hemorrhages of veins the writer has never seen it.

Injuries of the neck, exclusive of the spine, are infrequent. In seventeen years there were treated in the Presbyterian Hospital in

New York only twelve fresh anterior or lateral accidental wounds of the soft parts. Three were cases of attempted suicides. There were four wounds of the back of the neck—all contusions. While it is admitted that probably all such diagnoses have not been recorded, these figures indicate a low incidence. In the large city-owned hospitals, especially in the congested districts, these wounds are more numerous.

War wounds of the neck are rarely duplicated in civil life. They are characterized by much destruction by serious infection and by the presence of foreign bodies. Bayonet wounds correspond more closely to some of the wounds of civil life. Whale and Ramsay and others give excellent descriptions of war wounds of the neck and of their management.

Symptomatology.—Severe contusion on the side of the neck is shocking (a blow popular with pugilists) and a large hematoma may result. A serious contusion may rupture the larynx, trachea, or esophagus, or damage the spine. Suffocation from displacement or by a large hematoma may occur. The common features of obstruction to breathing are hemorrhage into the trachea with cough, hoarseness, dysphagia, and emphysema. Strangulation is a form of contusion. If the patient survives, the features mentioned are to be kept in mind. The commonest incised wound of the neck is probably that of the attempted suicide. These wounds usually lie transversely across the upper part of the neck, and as they are usually made with the chin up and by the right hand, they extend more into the left than into the right side of the neck.

The anterior transverse wounds may be between the hyoid bone and the mandible. If the hyoglossus and genioglossus muscles are divided, the tongue drops back and causes respiratory obstruction. It is important to hold the tongue forward and to suture it in its forward position. An incised wound may enter the pharynx and damage the epiglottis and cartilages. While a wound may sever the trachea, it may not reach the large vessels which lie relatively posteriorly and are protected in part by the sterno-mastoid muscles. Profuse bleeding may occur, however, from the anterior vessels and from the thyroid gland. The recurrent laryngeal nerve may be divided. Incised

wounds tend to gap, and sometimes the platysma muscle acts to roll in the edges.

The term cut throat applies to anterior and anterolateral incised wounds of the neck. The immediate dangers of anterior wounds are hemorrhage and asphyxia. Hemorrhage may cease as blood pressure falls, only to recur on motion or manipulation. With a deep wound it must not be assumed that because bleeding is not active it is securely arrested. Investigation is essential to assure control of obscure bleeding points. Asphyxia may be caused by the cartilage by the infolding of cut tissues, by a clot in the larynx or trachea, or by retraction of a completely severed trachea. The secondary dangers of an anterior wound are edema of the glottis, laryngitis, tracheitis, bronchitis, pneumonia, lung abscess, suppuration in the neck extending to the mediastinum, secondary hemorrhage, aphonia, and dysphagia. In the neck as elsewhere, a suppurative process usually implies an infectious thrombophlebitis of the accompanying veins and possible bacteremia. If the patient survives the hemorrhage, asphyxia, and shock, the commonest causes of death are pneumonia, mediastinitis, and bacteremia. Unrelieved edema of the glottis may be fatal. If conservative treatment does not allow a developing edema, tracheotomy can be performed.

Lateral incised wounds of the neck occur in fights and homicides and, if deep, may be the cause of serious hemorrhage and occasionally of arteriovenous or simple aneurysm. Lacerated wounds, both in war and in civil life, are most prone to infection. This is explained by the greater area of tissue contamination, the locking off of deep tissue spaces, the greater damage to the circulation of the affected tissue by the original trauma, the poorly supplied shredded parts, and the actual destruction of tissue which sloughs and interferes with nutrition and predisposes to bacterial growth. Such a wound is also more susceptible to tetanus and gas-producing infections. It may contain foreign bodies which become buried under torn parts. Dog bites usually represent superficial punctured but occasionally lacerated wounds of the throat. Deep penetrating or punctured wounds of the neck by missile or knife are often rapidly fatal, either from immediate arterial hemorrhage or from extravasation.

of blood perhaps only from a vein causing early respiratory obstruction by pressure. The supraclavicular region may be wounded by a downward stab causing damage to the brachial plexus the subclavian vessels the large lower neck vessels the thoracic duct and the lung.

Visceral Wounds—The serious dangers of wounds in the neck are hemorrhage suffocation infection pneumonitis irritation and secondary hemorrhage. Except for hemorrhage these dangers depend largely on the penetration of or the effect on the structures that are lined with mucous membrane. Infection from them is more serious and more difficult to control than infection through the wound from without. The serious results in the neck are edema of the glottis infections thrombophlebitis with bacteremia and with possible extension to the intracranial veins mediastinitis and secondary hemorrhage. Most secondary hemorrhages (usually from veins) occur in wounds badly contaminated from the mouth or the pharynx.

Wounds involving the floor of the mouth and the pharynx are accompanied by foul infection leakage of saliva difficulty of feeding discomfort slow healing and ultimate deformity. Esophageal wounds are due either to instrumentation within or to lateral penetrating wounds of the neck. If feasible the esophagus should be sutured in two layers by an approach in front of or behind the sternomastoid muscle. The operative approach should be drained and not sutured. Fluids may be given through a nasal tube but gastrostomy occasionally is needed after severe injuries of the neck mouth and throat. When the larynx or trachea is cut across there is a tendency for the two parts to separate. A forward and low position of the head and chin thus facilitates their approximation. If the larynx is badly damaged a temporary tracheotomy may be performed with subsequent careful repair of the larynx. Wounds affecting the larynx produce respiratory disturbance changes in the voice emphysema and blood on coughing. Localization is established by pain tenderness and the history of the injury.

Wounds of the trachea vary in degree. If it is only partially cut across separation is slight and primary suture may be indicated. If the division is complete the lower cut end

may retract beneath the sternum or be drawn in at each effort of inspiration when soft parts cover the orifice. If conditions are suitable attempt at suture should be made. If not the lower orifice should be sewed to the skin and a long tracheotomy tube inserted. Reconstruction of the trachea may be attempted later. Examination of these patients should include endoscopic examination introral and bimanual examinations and x-ray views of the pharynx and trachea if conditions permit.

The clinical picture of respiratory obstruction consists of great dyspnea cyanosis anxiety pain aphonia dysphagia a rapid full pulse and often with it in a fresh wound hemorrhage and in a later stage infection. When respiration is embarrassed hemorrhage increases when it is free hemorrhage decreases. Every hospital should be adequately prepared for quick tracheotomy. Laryngeal edema is the bugbear in cases of wounds in the neck. An oxygen tent may be helpful.

Treatment—The general principles of wound treatment apply to the neck and are modified only by the local anatomy and physiology. The immediate demands are control of hemorrhage prevention of suffocation and prevention of infection. One must be prepared to cope with shock and exsanguination and to prevent pneumonitis. The administration of tetanus antitoxin often is advisable. Severe venous bleeding can be controlled temporarily by direct pressure and packing. Arterial bleeding from a good sized vessel may not respond readily to pressure. Severe arterial bleeding may be controlled by digital pressure on the common carotid artery backward and inward against a vertebra. This digital pressure may need to be continued by relays of assistants until operation.

Take for example the case of a patient with a severe cut-throat injury who reaches the operating room about three hours after the occurrence of the accident with the hypopharynx cut open the epiglottis divided the breathing partly obstructed and the transverse wound gaping and filled with a tight pack of gauze temporarily controlling hemorrhage from the left anterior jugular and common facial veins and from the left facial or external maxillary artery. The nec

essary maneuvers may be enumerated as follows 1 Chloroform anesthesia has been a good agent in these cases but now probably is being largely supplanted by intravenously administered sodium pentothal or evipal combined with adequate airway 2 The skin is shaved cleansed and sterilized widely 3 The packing is removed slowly and replaced with more specific pressure or clamping as it comes out 4 The open viscera is adjusted so as to ease the breathing 5 The wound is enlarged if necessary 6 Gross foreign bodies are removed 7 Clots are removed and the wound is irrigated with normal saline solution without spilling any into the airway 8 The sterno-mastoid muscle is freed and retracted backward 9 The exact anatomy of the wound is carefully identified 10 Each vessel is slowly released clamped and ligated care being taken that the veins are ligated at each cut end and that the main artery that is affected is ligated 11 The epiglottis and the pharyngeal wall are sutured 12 The whole wound is again flushed with saline solution several gallons being used with considerable force 13 The muscles are sutured over the pharyngeal closure 14 If the wound is relatively clean with good hemostasis it may be closed loosely leaving in a soft rubber-dam drain but if badly contaminated and not dry no further closure is indicated Soft drains and a moist dressing then are applied If an anaerobic infection is feared or should develop daily zinc peroxide treatment of the wound should be used—provided the hollow viscera are securely closed

Before during or after the operation the larynx and trachea may be aspirated of blood and mucus Blood or plasma transfusions may be needed The after treatment includes elevation of the foot of the bed and the semi prone position of the patient so as to favor drainage from the trachea quiet relief of pain fluids given parenterally moist loose dressings and daily inspection and dressing of the wound In the prevention and in the treatment of wound infection the use of modern chemotherapy and of penicillin may be life saving

The essentials in the treatment of impending laryngeal edema (edema of the glottis) may be stated as follows preparation for emergency tracheotomy (but this operation

should be done sufficiently early to allow for a deliberate, careful technique under local anesthesia) cold moist compresses ice to such fluids parenterally quiet morphine with atropine and free drainage of the wound The question of the best position for the patient should be considered Elevation of the head and shoulders decreases congestion while lowering favors expectoration from the trachea which is apt to accumulate mucus below the narrowed glottis

The selection of the anesthetic is important for the patient with a serious injury or infection of the neck Irritation of the mucosa swallowing coughing struggling cyanosis congestion of the vessels increased secretion of saliva and of mucus all predispose to the spread of infection pneumonia edema of the larynx and hemorrhage While chloroform has its dangerous feature if it is cautiously administered it is a good anesthetic to employ in these cases Cyclopropane may prove to be the best The regional and local infiltration of novocain increases trismus and pressure obscures landmarks and is uncertain of success in the deep and complicated cases Ether by inhalation has obvious disadvantages Ether per rectum by the Gwathmey technique is an excellent anesthetic yet the induction is slow and an excitement stage is not infrequent Avertin even in full dosage would require supplementary inhalation anesthesia in many instances It is not needed with chloroform and besides the two together are dangerous Avertin with novocain does not lessen the disadvantages of novocain Nitrous oxide with oxygen might be used occasionally if limited to analgesia and if the cooperation of the patient is assured but for complete anesthesia and relaxation the necessarily closed method carries with it a relatively narrow margin of safety in the matter of cyanosis venous congestion and strain The question of direct laryngoscopy and of the passage of a tube into the trachea will arise in connection with these patients One must weigh the advantages of direct examination of sucking out accumulations from the trachea of intratracheal anesthesia (usually ether) and of insufflation against the disadvantages of hyperextension of the neck and of laryngeal trauma

ABSCESSSES AND TUMORS OF THE NECK

DEEP CERVICAL ABSCESS

Abscesses are particularly likely to occur in the deeper structures of the neck owing to the abundant lymphatic drainage from infected or potentially infected areas in the mouth and upper respiratory passages. Oral hygiene has done much to diminish the number of these infections, but the majority of cervical abscesses still arise from infected teeth and tonsils. In the past, the mortality from deep cervical abscesses has been unduly high; a mortality of 30 to 50 per cent being reported for such conditions as Ludwig's angina. This high mortality may be accounted for by several factors, chief among which is the anatomical peculiarity of the structures involved.

The importance of fascial planes in infections of the hands is now well established, but the importance of fascial planes in the diagnosis and treatment of infections of the neck is not so well understood. The fascial planes of the neck form well defined compartments and infection confined within these compartments may so obscure the usual signs associated with the accumulation of pus that the diagnosis may be delayed beyond the optimum time for drainage. It may also render ineffectual drainage which in other portions of the body would be effective. Pus confined within these compartments may accumulate sufficient pressure to obstruct respiration. The fascial planes may be effective in directing pus into the mediastinum. If one considers the ease with which

infection may spread to the central nervous system via the lymphatics or large vessel or to the mediastinum or to the lungs and vascular system, it is small wonder that infections of the neck may have an unusually high mortality. Early diagnosis with a thorough conception of the extent of the infection and the possible sequelae is essential if one is to avoid an unduly high mortality. This is rendered doubly difficult because the signs usually associated with the accumulation of pus elsewhere in the body may not be manifest with pus in the deeper structures of the neck. When the spread of the infection is limited to the lymphatics particularly the superficial lymphatics, palliative or expectant treatment may be safely employed. However, when the deeper fascial compartments of the neck are involved, successful temporization may be fatal.

Etiology.—It was formerly thought that the rapid and fatal termination of many infections of the cervical region was due to the peculiar virulence of the infecting organism. While this is undoubtedly a contributory factor, it has been repeatedly demonstrated that the same organisms in other portions of the body do not produce such violent manifestations. Almost all known organisms have at some time or other been described in deep abscesses of the neck. The majority of these abscesses are caused by a streptococcus which is frequently obtained in pure culture. Usually there is a mixed infection of streptococcus and staphylococcus. As Mosher has demonstrated, the greatest single source of these infections is, in or about the tonsils. Next in frequency are the teeth. Deep cervical abscesses have followed a great variety of injuries in or about the mouth.

Applied Anatomy.—The following brief résumé is based in part on the work of Mosher and is particularly pertinent to the spread of these infections of the neck. There are three fascial compartments in the upper part of the neck which are prone to be involved in the spread of infection, and which are in intimate relation to the sheath of the carotid artery and internal jugular vein. Beck has simplified this concept by considering these compartments as a trifolium, the stem of which is the sheath of the great vessels. These compartments are the pre-laryngeal, the submaxillary and the parapharyngeal. One or all of these fascial compartments may be involved.

The parapharyngeal space is a cone-shaped space with its base in relation to the skull and its apex at the jugular

foramen and with the apex at the greater cornu of the hyoid bone. Medially it is in intimate contact with the superior constrictor of the pharynx and the tonsillar fossa. The posterior portion is bounded by the retropharyngeal space. Its lateral surface is in relation with the retromandibular portion of the parotid gland which is not covered by fascia. The internal pterygoid muscle also forms part of its outer border. The pharyngomaxillary fossa is divided into two unequal compartments by the styloid process with its attached muscles. Infection of this space constitutes over one half of the deep infections of the neck. Because of its position it may be infected from the tonsillar fossa, mastoid, retropharyngeal glands, parotid molar teeth and nasal pharynx as well as by the invasion of pus from the parotid or submaxillary compartments. The intimate relation of the vessels which traverse this

cause of its position the carotid sheath may become infected from the parotid, submaxillary or pharyngomaxillary fascial compartments. The pharyngomaxillary compartment is, however, usually involved. Local signs are of little use in diagnosing infection of the carotid sheath or jugular thrombosis. Swelling and local tenderness over the vessels may be misleading as they are frequently caused by involved lymph nodes. The general symptoms indicating blood stream involvement such as chill and rapid elevation of temperature, are of more value. Blood cultures should be taken during and immu-

Fig. 447—Cross section of the neck through the second cervical vertebra showing the pharyngomaxillary fossa. (Courtesy of H. P. Mosher.)

compartment is of extreme importance. Pus in the pharyngomaxillary fossa may cause the lateral pharyngeal wall to bulge inward. Bulging of the lateral pharyngeal wall may be mistaken for a peritonsillar abscess although careful inspection will reveal that there is little swelling of the tonsils *per se*. Its intimate relation to the internal pterygoid muscle and pterygomandibular ligament frequently results in trismus as an early sign. There may be pus in the pharyngomaxillary space without external visible evidence and it may result in jugular phlebitis. Occasionally pus extends from the parotid into the pharyngomaxillary space or vice versa. The submaxillary compartment will be discussed under Ludwig's angina.

Carotid Sheath Infections and Jugular Thrombosis—It will be readily seen that be-

trated after the chill. If this precaution is not observed blood cultures may be negative in the presence of jugular thrombosis if the thrombus is already well formed. This is probably due to the complete plugging of the vessel with occasional liberation of emboli. Repeated chills and fever with evidence of involvement of the pharyngomaxillary space indicate jugular thrombosis and call for immediate intervention.

Treatment—The successful treatment of a deep cervical abscess depends on early diagnosis and early adequate drainage. The external signs of pus are unreliable. Fre-

quent inspection of the pharynx with a careful consideration of the development of symptoms will lead one to suspect the accumulation of pus. The greater cornu of the hyoid bone may be taken as a landmark from which the various compartments particularly the pharyngomaxillary fossa may be explored. Blind incisions over swollen areas may be misleading, anatomical structures must be recognized and pus sought for in definite anatomical spaces which are frequently much deeper than anticipated. For deep abscesses of the neck which have a tendency to descend for instance those along the carotid sheath Galloway suggests the performance of prophylactic mediastinotomy with gauze packing before drainage of the abscess proper. With this procedure mediastinitis is thought to be less likely to occur.

RETROPHARYNGEAL ABSCESS

Retropharyngeal abscess is most common in early childhood. It is situated beneath the prevertebral fascia and thus may extend downward into the mediastinum or laterally into the pharyngomaxillary space involving the sheath of the great vessels. This retropharyngeal swelling may protrude so far forward that as it extends down the posterior pharyngeal wall it may eventually cover the larynx and obstruct respiration. Symptoms may begin with fever and a croupy cough at which time there may be extreme difficulty in making out the boggy swelling of the posterior pharyngeal wall. It may be followed by dysphagia and dyspnea. Lateral roentgenograms of the cervical spine may be extremely helpful in making a diagnosis. The abscess should be incised and drained orally.

LUDWIG'S ANGINA

When a proper name is given to a previously unrecognized disease syndrome it may for a time serve the very useful purpose of calling attention to the significance of the syndrome but in the end it is likely to add to the general confusion as other signs and symptoms are added and a variety of unassociated conditions are inappropriately grouped under one heading. Ludwig's angina has proved no exception. The term is used to cover a variety of infections arising in the buccal cavity and related structures involving the floor of the mouth and extending from this to the neck and submaxillary regions.

There are many references in the older literature to similar conditions of the throat from Paulus Aegnetus

down through the Greek and Arabian physicians including Hippocrates, Galen, Celsus, Aretaeus, Rhazes and others. Gollberg in 1739-1746 gave an account of "putrid sore throat." Gensoul of Lyons in 1830 published an excellent account of the disease. In 1838 Ludwig then a professor at Stuttgart in Wurtemberg published a report on gangrenous inflammation of the neck which report attracted considerable attention probably in part because Queen Catherine of Wurtemberg died of this malady. In 1837 Cameron gave it the name of *angra Ludovici*. Since that time most infections in the region of the mouth, pharynx and neck especially those that terminate fatally have gone under the name of Ludwig's angina. The French Surgical Society in 1899 was particularly concerned in a controversy between Volton and D'Arme as to whether Ludwig's angina should be recognized as a separate complete entity. The consensus of opinion at the present time is that it should and does constitute a clinical and pathologic entity and deserves special consideration.

Etiology and Pathology.—The problem of the high mortality and the cause of death has been paramount. The peculiar virulence and rapid progress of the infection have frequently led to the conclusion that a peculiarly virulent type of bacteria must be involved. Septic intoxication has frequently been held responsible for the fatal outcome. However as was pointed out by T. Turner Thomas in an excellent article "If septic intoxication is the essential cause of death then the especially high mortality of this condition must be explained by the presence of a rare and especially virulent infection. A variety of organisms have been found such as *staphylococcus*, *streptococcus pneumoniae*, *B. coli*, *gas bacillus* and all mixtures of the same. *Streptococcus* predominating. The high mortality has been shown to be due to the anatomical peculiarities of the region and to the extension of the phlegmonous inflammation to the larynx and lungs. In some of the fatal cases pneumonia and pleurisy have developed and a few patients have died of septic intoxication but in the majority there has been an interference with respiration. Dyspnea is noted in nearly all the fatal cases and if sudden death does not result from obstruction in the region of the glottis there is usually evidence of involvement of the lungs.

Applied Anatomy.—In order to obtain a better understanding of the mechanism involved in the spread of infection in Ludwig's angina the buccal cavity may be considered as a closed box. A detailed description is unnecessary as it is readily seen that the bony

structures such as the jaw teeth and palate sharply limit any swelling which occurs within the buccal cavity. Extension downward is limited by the diaphragm formed by the mylohyoid and the other muscles and ligaments attached to the hyoid bone which is relatively immovable. It is therefore obvious that when swelling occurs in the structures of the floor of

Fig. 418—Semiagrammatic sketch showing the diaphragm formed by the structures in the floor of the mouth.

the mouth or tongue, the buccal cavity is soon filled except for its posterior portion. As soon as swelling reaches this region there is obstruction of the respiratory passages. This mechanical feature alone undoubtedly accounts for a large percentage of the fatalities. A considerable number of the patients afflicted with Ludwig's angina die from a pulmonary infection which is probably explained by the extension and invasion of bacteria to the larynx coupled with the difficulties of respiration. The above anatomical features explain the mechanism of Ludwig's angina when the infection arises in the mouth. However, there has been some controversy as to whether the infection begins within the mouth or arises in the lymph nodes under the submaxillary triangle. Certainly it frequently begins within the mouth involving the structures above the mylohyoid muscle and later extends to the submaxillary triangle. This is accounted for by the fact that the opening along which the pus travels is formed by the submaxillary gland, the inner portion of which passes around the posterior border of the mylohyoid muscle thus connecting the neck with the floor of the mouth. Conversely, infection arising in the neck and forming pus in the submaxillary glands may extend by this route into the floor of the mouth. Occasionally pus accumulates nearer the midline in the submental region in which event it may lie either above or below the geniohyoid muscle but always underneath the mylohyoid.

Diagnosis.—An infection of the neck in the submental or submaxillary regions does not constitute Ludwig's angina. However, by extension from the submaxillary region

around the mylohyoid muscle to the floor of the mouth it may become Ludwig's angina. In Ludwig's angina the usual signs of the accumulation of pus, such as redness, fluctuation or localization are late. This is readily understood when it is realized that the infection is separated from the subcutaneous tissue by the mylohyoid muscle and dense fascial layers. However, there is frequently a brassy edema of the subcutaneous tissue. Careful palpation of the floor of the mouth may reveal evidence of an inflammatory reaction. Swallowing may be painful. Later there may be obvious evidence of swelling of the tongue and structures of the floor of the mouth. The disease may be subacute for several days and the general systemic manifestations may vary from moderate to violent. As the condition progresses, the symptoms may increase in severity out of all pro-

Fig. 419—Semiagrammatic sketch showing the location of pus in "Ludwig's angina" above or below the geniohyoid muscle. (Note the box-like compartment filled by the tongue and adjacent structures and the case with which inflammation extends to the region of the larynx.)

portion to the increased area infected and this usually indicates invasion of the larynx or lungs rather than septic intoxication.

Treatment.—Early diagnosis and early treatment are essential. The external signs of inflammation in the neck are of little use

and are more often misleading. One should not wait for fluctuation as a sign of pus or it will be too late. The pus is usually deep and cannot be palpated on the surface. It is possible to anticipate the diagnosis by frequent examinations for involvement of definite anatomical spaces especially if the floor of the mouth is watched for evidence of inflammation. It is important to locate the primary source of infection if possible as occasionally the disease has been aborted by adequate drainage of the primary lesion. Superficial abscesses may be drained through the mouth otherwise adequate drainage through the submaxillary fossa is indicated. The essentials of successful treatment are early and adequate incision with wide exposure and recognition of the structures involved. The necessity for immediate tracheotomy should be anticipated. General anesthesia may be dangerous owing to respiratory obstruction.

RECLUS' DISEASE

(Woody or Ligneous Phlegmon)

Paul Reclus in 1896 reported five cases characterized by a hard board like swelling of the neck thought to be due to a chronic inflammation involving connective tissue muscle and fascia. The etiology of this condition is still unknown although a variety of bacteria of low virulence have been grown from the yellow tinged fluid obtained on incision. While the cases reported by Reclus occurred in the neck similar lesions have been reported in various parts of the body. Some of these have been found to have deep underlying tumors such as carcinoma and sarcoma while others have developed into osteomyelitis. About 75 per cent of the patients recover although when the disease occurs in the neck there is a slightly higher mortality. Whether this condition deserves a place as a distinct disease entity is open to question. It usually runs a chronic course although some patients recover in a short time following incision. Small abscesses may form and should be drained. Since it seems to be impossible to distinguish this condition from certain slow growing carcinomas in the deeper structures the diagnosis should be regarded with suspicion until every effort has been made to rule out the other possible etiological factors.

BRANCHIOGENIC CARCINOMA

In a great majority of cases carcinoma of the neck is metastatic in the cervical lymph nodes and the primary source of origin is usually obvious. There is a second group of cases of carcinoma metastatic in the cervical lymph nodes in which it is extremely difficult to find the primary lesion. A careful search of the mouth nasopharynx and accessory nasal sinuses may not reveal the primary tumor. Not infrequently the tumor arises deep in the tonsillar crypt and extends to the neck the primary lesion remaining so small as to be unnoticed for a considerable period. Palpation of the tonsil in these instances may be helpful. However there is a third group of cases of carcinoma occurring in the neck in which removal of the tumor has resulted in permanent cure or in which no primary focus after years has been discovered. The general term cryptogenic carcinoma has been applied to these tumors and while it has been thought that the majority of them are of branchiogenic origin it is possible that they have arisen from some other aberrant tissue e.g. from the salivary glands or the thyroid. Space does not permit a complete discussion of the complicated anatomy of the branchial remnants and for a detailed description the reader is referred to the article published by Keith in 1909. Carcinoma may arise from the epithelium of any of the branchial remnants and there may be no definite histologic characteristics by which it may be identified. However as this is the least frequent origin of cancer in the neck all other possible sources such as a concealed primary growth in the oral cavity should be ruled out. Stout states that the tumors are commonly composed of squamous or transitional cells with little or no tendency toward keratinization or pearl formation but with a marked tendency to form masses with central necrosis of cells giving rise to cavities lined with tumor cells. The tumor generally starts deep in the neck near the bifurcation of the common carotid artery and either extends directly or metastasizes to the adjacent lymph nodes. A branchial cyst usually arises from the third branchial cleft or at the level of the hyoid bone. When it arises from the second branchial cleft it is situated below the mastoid and may project into the mouth.

of the thyroid gland and malignant disease of the mediastinal glands and by trauma to the recurrent nerves during or after thyroidectomy

Pathology—In addition to the causative factors, loss of function of the abductor muscles of the vocal cords and interference with the respiratory function may be noted

Symptomatology—The voice may be normal but the patient will speak as though breathless. The outstanding symptom is inspiratory dyspnea due to failure of the vocal cords to separate during inspiration. Expiration is normal

Diagnosis—By mirror laryngoscopy the vocal cords are found in adduction. On inspiration there is no separation and only a slight drawing downward and inward of the edges of the cords. The cause of the paralysis must be determined and differentiated from cricoarytenoid ankylosis

The prognosis is unfavorable as sudden death from asphyxia is always imminent. If paralysis is complete there is no hope of improvement; if partial as in syphilis there may be benefit from treatment

Treatment consists of tracheotomy if there is obstructive laryngeal dyspnea. Removal of the cause rarely is possible. Ankylosis of the nerves in cases of injury has not been successful. The use of a cone or tracheal cannula is practicable. Ventriculo-cordectomy has not been successful. Submucous resection has been superseded by either mobilization and lateral fixation of the arytenoid cartilage (Lang) or arytenoidectomy and lateral fixation of the vocal cord (Kelly). These procedures are highly successful

Infection of the larynx becomes of surgical importance when the inflammatory changes and associated edema produce stenosis and necessitate tracheotomy. Lack of space will not permit a detailed description of the causes or the pathologic changes observed

Acute Inflammatory Edema of the Larynx (Edema of the Glottis)—**Definition**—Stenosis of the larynx resulting from acute inflammation

Etiology—The causes may be acute laryngitis, acute infectious diseases, acute inflammatory processes involving surrounding structures, abscess of the larynx, acute

septic laryngotracheobronchitis, injuries or wounds of the larynx or neck, burns or scalds of the larynx, inhalation of irritating vapors, chondritis and perichondritis, chronic diseases or foreign bodies

Pathology—The changes are those of the underlying cause together with inflammation and edema involving the submucous tissues above and below the vocal cords

Symptomatology includes obstructive laryngeal dyspnea with disturbances of the voice and general systemic reactions. *Obstructive laryngeal dyspnea* is characterized by inspiratory indrawing of the soft tissues of the thoracic cage at the suprasternal notch, epigastrium and intercostal supraclavicular and infraclavicular spaces with restlessness, ash gray pallor and increasing pulse and respiratory rates. Cynosis occurs late and is a danger signal

Diagnosis—The signs of obstructive laryngeal dyspnea are diagnostic. Inspection of the larynx, palpation of the neck, roentgen examinations, general systemic studies and the history are usually required in order to arrive at an etiologic diagnosis

The prognosis depends on the cause. The dyspnea can be relieved by tracheotomy

Treatment—In simple cases inhalation of medicated vapors, the use of the oxygen tent and general medical measures may suffice. *Sedatives must be avoided*. If dyspnea is marked tracheotomy becomes necessary. This should not be delayed until an etiologic diagnosis is made but must be promptly executed. *Tracheotomy* consists of incision into the trachea in the midline of the neck below the first tracheal ring, preferably below the second ring. General anesthesia is contraindicated. *Tracheotomy* should be performed early so that it can be carried out in an orderly manner. Delay is dangerous and commonly results in a poorly performed operation. So-called high tracheotomy is an improper operation which although life saving is commonly followed by chronic stenosis. The skin incision should extend from the thyroid notch to the suprasternal notch; the thyroid isthmus should be incised and ligated; two or three tracheal rings should be cut. The tracheotomic cannula should be of proper shape and size. The wound should not be sutured but left open. The after care consists of keeping the air

way open by wiping away coughed up secretions cleaning the inner cannula and aspirating secretions from the trachea through the cannula. With crusting of secretions bronchoscopy through the tracheostomic fistula may become necessary in order to keep the airway open.

Non-inflammatory edema of the larynx as observed in cases of nephritis angioneurotic edema and passive congestion due to venous obstruction becomes of surgical importance only when tracheotomy is required to relieve obstructive laryngeal dyspnea.

Chronic Stenosis of the Larynx (Cicatricial Stenosis of the Larynx).—Definition.—Narrowing of the laryngeal airway by cicatricial changes.

Etiology.—The most common cause is improperly performed tracheotomy or improper after-care. Other causes may be syphilis tuberculosis injuries chondritis perichondritis and abscess.

Pathology.—The normal structures are replaced by cicatricial tissue with narrowing of the airway fixation of the vocal cords and often loss of a part of the normal supporting cartilaginous framework of the larynx (Fig. 450). If tracheotomy has been improperly performed a portion of the cricoid or thyroid cartilage may be lacking.

Symptomatology.—The chief symptom is an inability to secure any or sufficient air through the normal airway. Voice disturbances vary from hoarseness to aphonia. There is an inability to decannulate.

Diagnosis.—*Examination of the larynx* reveals a narrowing or obliteration of the airway, the extent and degree being determined by direct laryngoscopy, palpation of the neck and roentgen examination. Retrograde laryngoscopy and esophagoscopy may be necessary.

The *prognosis* is good if there is little loss of cartilage but months or years of treatment may be necessary to secure a good result.

Treatment.—In moderate degrees of stenosis laryngoscopic dilation may be adequate. In marked cases surgery must be resorted to and consists of laryngostomy, removal of sufficient cicatricial tissue to reestablish the airway and the use of some form of apparatus to maintain the airway during the process of healing. In the open method

a trough corresponding to the stenosed airway is maintained by the use of a dilating apparatus. When a satisfactory airway has been secured the fistula is closed by plastic operation. In the closed method the airway is reestablished a rubber tube is transfixed in the larynx with silver wire and the neck closed (Fig. 450). The rubber tube is removed perorally after a number of weeks or months.

DISEASES OF THE TRACHEA AND BRONCHI (Exclusive of Neoplasms)

Injuries to the bronchi are rare and are usually associated with extensive pulmonary damage. Injuries to the trachea are more common, falls, blows or wounds of the neck being the common causes. The tracheal rings may be incised or fractured or the interannular membrane may be lacerated. Dyspnea is present depending on the degree of narrowing of the airway. If vessels have been injured there is hemorrhage. Empyema may result from laceration of the trachea. Pain on swallowing may be severe. The history with the local evidences of injury is usually diagnostic. Bronchoscopy may be necessary. The prognosis depends on the extent of the injury and the involvement of the surrounding structures notably blood vessels and esophagus.

Treatment.—Hemorrhage should be controlled first. Tracheotomy is indicated for dyspnea. Incised wounds should be repaired with drainage. Cicatricial stenosis is treated by dilation or by tracheostomy performed as in laryngostomy.

Infection of the Trachea and Bronchi.—Simple catarrhal infections present no surgical problems. Chronic infections such as tuberculosis and syphilis are of surgical importance if stenosis results. Pulmonary suppurations namely *abscess* and *bronchiectasis* are of importance bronchoscopically particularly from a surgical standpoint (see section on Bronchiectasis and Lung Abscess).

FORGIVEN BODIES IN THE AIR PASSAGES

The lodgment of a foreign body in the larynx, trachea or bronchi is a common accident. The most common cause is carelessness in holding objects other than foods in

the mouth. These are commonly aspirated with a deep inspiration when the person is laughing, coughing, sneezing, singing or talking. The pathologic changes depend on the character and location of the object, the length of sojourn and whether or not there is obstruction. Recent non-obstructing foreign bodies may produce no changes other than slight inflammation at the point of lodgment. Obstructing foreign bodies will ultimately cause suppuration and bronchiectasis. The initial or immediate symptoms are choking, gagging and coughing. The subsequent symptoms depend on the size,

non-obstructing foreign bodies may produce no symptoms, the initial symptoms being followed by a *symptomless interval*. The *asthmatic wheeze* is an important sign. If a foreign body produces partial bronchial obstruction, there is often an obstructive *emphysema*. In complete bronchial obstruction there is obstructive atelectasis. Partial obstruction is usually produced by nuts, seeds and shells that do not swell in the presence of moisture, whereas complete obstruction is produced by globular foreign bodies and vegetable seeds that swell when moistened.

Fig. 451.—A typical example of an obscure lesion of the chest requiring bronchoscopy as an aid in diagnosis. The patient, aged nine years, had been ill, with irregular fever, cough, slight expectoration and pain in the right side of the chest for about three months. The history was practically negative. By physical and roentgen examination the lesion was localized to the right lower lobe. The heart was drawn to the right (a). It was necessary to differentiate between bronchial obstruction with pulmonary atelectasis and bronchiectasis with pulmonary fibrosis. At bronchoscopy the bronchi were found patent and larger than normal. Roentgenograms made following the bronchoscopic instillation of iodized oil into both lower lobe bronchi revealed extensive bronchiectasis involving the lower lobe of the right lung with a normal left lower lobe bronchus (b). Lobectomy was recommended. (Films by Dr. J. T. Farrell, Jr.)

shape and character of the foreign body and the point of lodgment.

Foreign Bodies in the Larynx.—The common symptoms are dyspnea and disturbances in the voice. There may be a cough and wheezing. Large, obstructive foreign bodies may produce asphyxiation.

Foreign Bodies in the Trachea.—Migratory foreign bodies produce paroxysmal coughing. An audible slap and palpatory thud may be elicited. Dyspnea and wheezing respiration may be present. If the foreign body is obstructive, there is commonly bilateral obstructive emphysema.

Foreign Bodies in the Bronchi.—Small

A history of initial symptoms of choking and gagging while holding something in the mouth and the occurrence of a wheeze are practically pathognomonic of the presence of a foreign body. With clinical and roentgen evidences of bronchial obstruction a positive diagnosis can be made in practically every case. In the case of a metallic object the roentgen finding should be conclusive. Over 98 per cent of foreign bodies can be safely removed. Peroral endoscopic removal is the only method worthy of consideration.

Peroral endoscopy, direct visualization of the interior of the trachea and larger bronchi, is possible by the use of specially

illuminated rigid hollow tubes. These are introduced through the mouth and serve as specula to draw aside structures that obstruct the view or bring them into the line of vision. The direct laryngoscope is a laryngeal speculum; the bronchoscope is a tracheal or bronchial speculum.

The smaller bronchial subdivisions cannot be entered bronchoscopically; much information may be secured, however, by palpation with forceps, by aspiration of secretion with the aid of straight and curved flexible

instrument in intratracheal insufflation and anesthesia.

Instruments—A special instrumentarium is necessary. Certain instruments are regularly used in the common procedures, while other instruments are required only in special cases. The normal air passages cannot be dilated beyond their normal caliber. It is therefore necessary to have special sized instruments for infants, children and adult.

Training—Acquiring skill in the use of endoscopic instruments can be secured only

Fig. 432.—Introduction of the bronchoscope. The patient is recumbent with head and shoulders extending beyond the end of the table. The head is supported by the left hand of the assistant. The mouth gag is in the left angle of the patient's mouth. The shoulders are supported by an assistant. The direct laryngoscope is held in the operator's left hand, exposing the larynx. The bronchoscope is held in the right hand of the operator, inserted through a laryngoscope and passed through the larynx into the trachea. As soon as the distal end of the bronchoscope has passed beyond the vocal cords the laryngoscope is removed. The bronchoscope has the latex cord and an aspirating tube attached. An additional independent aspirating tube held by the nurse is ready for use.

tipped aspirating tubes and by the bronchoscopic introduction of opaque materials. Bronchocopy is the only method for the removal of foreign bodies from the air passages and it has also made possible outstanding contributions to the diagnosis and treatment of pulmonary diseases. Noteworthy among these are the early and positive diagnosis of bronchial carcinoma made possible by bronchoscopic removal of tissue for histologic examination and the bronchoscopic treatment of pulmonary abscess. In addition direct laryngoscopy plays an impor-

tant part in educating the eyes and the fingers. As this cannot be secured on the living patient the fundamental principles are best taught on the cadaver. This should be supplemented by practice on the rubber tube manikin. When skill and proficiency have been attained experience should be secured on narcotized dogs so that the normal physiologic movements may be observed and studied.

Anesthesia—General anesthesia is not necessary and is often undesirable but patients are commonly given a preliminary

sedative. Immediately before the operation the larynx of the adult patient is cocaineized. In children, however, the use of cocaine is considered unsafe.

Technic of Introduction—The patient should be in the dorsally recumbent position with the head and shoulders extending beyond the end of the table. The head is supported by the left hand of an assistant who is seated at the patient's right, with his right hand the assistant holds the mouth gag in the left angle of the patient's mouth. The shoulders are supported by a second assistant. The operator exposes the larynx with the direct laryngoscope held in the left hand, with his right hand he then introduces the tip of the bronchoscope through the laryngoscope into the trachea (Fig. 450). The laryngoscope is removed and bronchoscopy is done. It is not within the scope of this article to discuss the detailed technic of the various procedures involved.

NEOPLASMS OF THE LARYNX

Neoplasms of the larynx may seriously interfere with the voice and the airway, and by extension compromise the adjacent vital structures. The chief tumors arise on or near epithelial surfaces underlying and supporting tissues contribute relatively fewer and less serious new growths.

MAIGNANT TUMORS

I. Carcinoma is of outstanding importance. The intrinsic form usually advertises its presence by hoarseness that should lead to its diagnosis early enough to be curable in over 80 per cent of cases with a service-

able voice and a natural airway. When neglected, overlooked or temporized with, carcinoma of the larynx produces one of the most desperate end states to be seen in medicine.

Etiology—No specific agents have been implicated as important factors. A general predisposition plus some local irritation is favored here as elsewhere as the cause of cancer. Hot drinks and hot foods have some presumptive evidence for their role in post-cricoid cancer. Smoking, which has a rather definite place in the development of lingual and oral cancer, seems also to be of some importance here.

Age—Most patients with cancer of the larynx are past fifty years of age. The disease rarely occurs before forty, but cases have been reported in the second decade of life.

Sex—Men are most commonly attacked, although post-cricoid carcinoma occurs much more often in women and at the earlier age of thirty or forty years.

Pathology—a. *Intralaryngeal carcinoma* may be divided after Hnuttant into four groups which differ from each other in their origin, location, symptoms, relative malignancy, prognosis and treatment.

1. **Cordil tumors** comprise the largest percentage of laryngeal carcinomas and offer the most favorable outlook. The middle or anterior third is most often attacked. The lesion may be papillomatous, fungating, nodular or ulcerating with varying degrees of deeper infiltration. Since these neoplasms arise from flat pavement epithelium, the majority are of relatively mature squamous cell type and of low grade malignancy, though the anaplastic cell type occurs in a small percentage of cases. The neoplasm may extend above the surface or beneath the mucosa or it may deeply infiltrate the cord and adjacent structures. It grows slowly and spreads late because of two factors: one is the mature cell type and the other the scant lymphatics with few anastomoses and limited drainage of the tendinous cord structure and adjacent larynx. In time one or both cords may become infiltrated and fixed and cancer cells may spread beyond the cord region where their growth is much more rapid, resulting in a ruthless attack on adjacent structures. The cartilages may become

eroded the larynx filled and the airway blocked. The cervical glands become involved first as separate hard nodules later as large fixed and even ulcerated and bleeding masses. Spread posteriorly involves the larynx and the esophagus and overruns the rim of the glottis into the hypopharynx obstructing the esophagus. The great vessels of the neck or their important branches may be involved. Distant or general metastases are rarely important before the terminal stage.

2 Subglottic carcinomas are relatively common are usually mature celled radioresistant and well advanced when diagnosed and are best treated by laryngectomy or hemilaryngectomy.

3 Cancer of the false cords or vestibule is more often embryonal in type and invasive, it early extends beyond the larynx and it responds fairly well to irradiation.

4 Cancer of the ventricle of Morgagni is rare. It usually is of hornifying cell type infiltrating and radioresistant and is best treated by laryngectomy.

b *Extrinsic carcinoma* of the larynx arises from the epiglottis the arytenoids or aryepiglottic folds or the upper or posterior surface of the cricoid and occurs as an extension beyond the larynx of a primarily intrinsic growth. Many of these have the essential character of tumors of the oropharynx. They are much more malignant in type as a rule of anaplastic or transitional cells they extend rapidly locally and give early metastases to the regional lymph glands. The airway and cords are involved later the food passages earlier than in the intrinsic group and in time the growth may fill the larynx lower pharynx and upper esophagus and may fix the glands and deep structures of the neck in one indurated even externally ulcerating mass.

Symptoms first arise from interference with the voice and respiration especially in the intrinsic form. Later they are due to involvement of the esophagus and the secondary effects of ulceration infection and regional nerve involvement. *Hoarseness* is early in intrinsic cancer and persistent becoming progressively worse. It is a warning not to be ignored while the condition is yet curable. Vocal fatigue and poor voice control precede or accompany hoarseness and

rest may temporarily lessen the dysphonia. Subglottic lesions may for a time only muffle the voice and in primarily extrinsic forms voice changes may be quite late. *Dyspnea* is a relatively late symptom but all too commonly is the first symptom leading the patient to seek medical attention. It may progress gradually but there may be acute respiratory difficulty due to a superimposed infection or edema. *Dyspnea* may be distressing and tracheotomy will be required in advanced cases. *Dysphagia* occurs late and only in extrinsic forms. It arises from obstruction or fixation of the esophagus and is most marked in the posterior forms. *Discomfort* may come early and there may be a feeling of sticking or a sense of a foreign body, but real pain is late. Rarely occurs in intrinsic forms and is caused by ulceration infection or nerve involvement. Not infrequently it is referred toward the ear of the affected side. *Cough* may occur from reflex irritation. Later it is due to esophageal obstruction with overflow of saliva or food into the respiratory tract. Symptoms of an advanced stage are palpable cervical glands cachexia loss of weight fetor uris hemorrhage and sepsis.

Diagnosis should not be difficult when the condition is once suspected. Other causes of hoarseness especially should be ruled out. Examination by laryngeal mirror or by direct laryngoscopy shows an uneven cord with a grayish rough nodular or dimpled surface or a papillomatous or infiltrating mass with the cord lagging or fixed. If the disease is advanced Biopsy should be performed under direct laryngoscopy but only when both the surgeon and the patient are prepared for the operative procedure which may necessarily follow. The importance of a correct diagnosis far outweighs the possible dangers of this procedure.

Carcinoma must be differentiated from chronic laryngitis and benign tumors and especially from tuberculosis and syphilis with which it may coexist. Benign tumors do not infiltrate rarely fix ulcerate only late if at all and run a simple course. Microscopic examination may be necessary to determine their type. Inflammatory lesions are usually not focal but diffuse are associated with sinus pharyngeal or systemic disease and improve under rest and proper

treatment Tuberculosis as a rule produces catarrhal thickening of the cords or shallow ulcerations and papillary hypertrophy in the interarytenoid space rarely involved in cancer and characteristic rounded or pyriform swellings over the cartilages The lesions are usually pale The condition may be painful and is associated with active pulmonary disease Syphilitic lesions are rarely sharply localized are hyperplastic or ulcerated and are darker They give positive serum tests and quickly respond to specific therapy especially iodides Leukoplakia of the larynx is usually a diffuse grayish thickening overlying the cords which occasionally can be differentiated only microscopically Sometimes it is a precursor of cancer

Treatment—Peroral removal of a very small growth with direct laryngoscopy or suspension can be accomplished with slight hazard and no important mutilation of the vocal apparatus Microscopic study however indicates that an intrinsic growth may infiltrate 0.75 cm beyond its apparent border and usually no less than that area of grossly healthy tissue should be removed For that reason peroral removal is not generally considered to provide adequate safety

Laryngofissure is the nearly ideal treatment in proper cases as it will effect a cure in over 85 per cent with a natural airway and a usable voice It should be performed in early intrinsic cases usually involving one cord away from its posterior border and without marked fixation The writer believes with St Clair Thomson that its indications should be widened at the expense of somewhat greater safety because when it is successful it leaves the patient a nearly normal person for whom life may still hold full zest The same can hardly be said for laryngectomy Even growths with some fixation or involving the anterior commissure or partially subglottic may be so treated with reasonable hope of success if clinically and histologically of low grade malignancy

The technic is simple and the operative mortality below 1 per cent A midline incision is made from the hyoid bone nearly to the sternum through skin and fascia and so encounters no important bleeding A low tracheotomy is usually done and the larynx is entered exactly in the midline The wing

of the thyroid cartilage on the affected side is separated from its perichondrium and removed or it may be left with only the medial perichondrium separated The affected soft tissues medial to the cartilage including cord and ventricular band as far back as the arytenoid cartilage are resected Closure may be partial or complete A feeding tube may be required though frequently it is not necessary and the tracheotomy tube may be removed at once or after a few days

Laryngectomy is more likely to eradicate malignant disease than the simpler operations A limited number of surgeons have developed a technic that in selected series has reduced the operative mortality to 1 per cent and has given 74 per cent of five year cures The patient after operation must breathe through a tracheal neck fistula or a tube is subject to the added danger of respiratory disease and finds heavy labor difficult Often the patient learns to produce a useful buccal or pharyngeal voice or may do satisfactorily with an artificial mechanism

Briefly the technic of operation is as follows The skin and superficial fascia are divided in the midline The anterior strap muscles are pushed aside or divided the larynx is completely skeletonized and is divided intact from the trachea pharynx and esophagus and the defect is closed in layers Great care is taken to prevent aspiration into the trachea and abundant drainage is provided The tracheal stump is united to the skin A feeding tube is left in the esophagus for one or two weeks Meticulous after care and continuous nursing attention are required The operation and after-care have been much simplified by leaving the strap muscles in place removing the cartilage after elevation of the perichondrium and leaving the mucosa on the posterior wall of the cricoid This gives much easier closure usually without leakage or infection and a smoother convalescence

Irradiation has been again advocated on the basis of improved technic which may allow its administration without injury to the cartilages It may be given by high voltage roentgen ray well filtered and at a distance in frequently repeated small doses (Coutard) or by using similarly large amounts of well filtered radium (Berven), or by direct implantation of radium or ra-

don seeds after resection of cartilage. The best statistics of five year cures by these methods are under 30 per cent and it does not seem justifiable to the writer to so treat intrinsic carcinoma of the cords suitable for laryngofissure. Even laryngectomy seems preferable unless the growth has extended beyond the larynx or unless other conditions like age, diabetes or tuberculosis make operation hazardous or seriously reduce the patient's expectancy.

II Sarcoma occurs rarely in the larynx though previously it was diagnosed with relative frequency probably as a result of error in histologic interpretation. In the larynx sarcoma occurs in the more benign types especially fibrosarcoma. It also occurs in later age groups than sarcoma elsewhere and rarely metastasizes. Operative removal which follows that outlined for carcinoma should be relatively radical and has been quite successful.

BENIGN TUMORS

Benign tumors of the larynx usually have an important effect on the voice and may seriously interfere with breathing. Nearly always they require destruction or removal.

Pathology—These tumors do not infiltrate the deeper structures or give local or distant metastases.

A Papillomas are perhaps the most important. Two types occur.

1 In adults they occur as single or multiple fibrous growths covered with piled up epithelium and appearing as grayish rough rounded wart like or even pedunculated masses. They spring from the cords or any part of the larynx and tend to recur repeatedly.

2 Papillomas in children somewhat resemble common warts in their histology, tendency to recurrence, auto-inoculability and tendency to spontaneous disappearance. They occur as numerous single or branching masses of piled up epithelium with a moderate fibrous stroma springing from the cords or any part of the larynx, trachea, bronchi or even the margins of a tracheotomy wound. They may occur as scattered growths or may completely fill the larynx as a grayish grape like mass.

B Other benign tumors include *angiomas* which may be globular or pedunculated.

They usually include much fibrous stroma and usually remain small. *Fibromas* are small, soft, smooth and red and usually arise from the cords. Some of these arise from granulomatous organization of hematomas which occur chiefly as a result of vocal trauma. *Lymphomas* may be benign and non-recurring but may be associated with a general lymphomatosis. *Adenomas* or cystadenomas may reach a considerable size in the larynx. *Myxomas*, *lipomas*, *chondromas*, *osteomas* and *neurofibromas* occur rarely. *Congenital* cysts are to be thought of in asphyxia of the newborn. Aberrant thyroid tissue does occur but is rare in the larynx. Hematomas, tophi, amyloid masses and edematous polypi may simulate tumors. Singer's nodes and contact ulcer granulations are reactions to vocal trauma.

Symptoms—First there is vocal disturbance with early huskiness, an unstable voice, easy fatigability, increasing hoarseness or even aphonia. Croupiness and cough are likely to be present with acute infections of the upper respiratory tract. Dyspnea may occur as a late symptom of obstruction and may be of acute onset as a result of edema or infection. If arising elsewhere in the larynx than from the cords a benign tumor may attain a relatively large size without symptoms.

Diagnosis is made on the basis of the symptoms with the typical appearance on mirror examination or by direct laryngoscopy. Microscopic examination of tissue removed by forceps may be necessary for the final diagnosis. Benign tumors of the larynx are to be differentiated from each other from carcinoma and from chronic inflammations especially tuberculosis and syphilis. Again the microscope may be necessary for the final decision.

Prognosis—Usually these tumors are not dangerous to life if properly treated. Some as for instance papillomas may lead to death by asphyxia and the removal of others may seriously affect the voice or lead to laryngeal stenosis.

Treatment of benign tumors of the larynx should usually be surgical removal by snares or forceps used under guidance of a laryngeal mirror or by direct laryngoscopy. Rarely is laryngofissure required. Irradiation is the treatment of choice of lym-

phomas and possibly of some papillomas. Diathermy if used with great caution may be valuable. In any case great care is necessary not to injure the cords or cricoarytenoid articulation. Papillomas should be removed from the intact cords with cutting or cup forceps rarely with punch forceps. Very careful surgical diathermy tends to prevent recurrence though it may easily injure the vocal cords. In children radium in small amounts has been advocated for papillomas though its use has led to adhesions and stenosis. Roentgen ray likewise has been used in small doses well filtered. Sex hormone therapy sometimes produces striking remissions. Ultimate spontaneous recovery in children

is the rule so that measures radical enough to injure the airway or voice should not be employed. Tracheotomy should not be delayed when dyspnea begins with papillomas in a child as asphyxia may quickly supervene.

XI. THE BREAST

ANOMALIES AND INFECTIONS OF THE BREAST

The class of animals called *mammalia* is distinguished by the nourishment of the young by milk secreted by the breast. In human beings this organ especially in the female reaches a high degree of differentiation and is subject to extreme physiologic variations and many important diseases of surgical interest. For a clear understanding of these certain anatomical and physiologic facts are necessary.

The breast is embryologically closely related to the sweat glands and the differentiation from these is not so great but that certain epithelial tumors of the breasts have similar histologic characteristics. In particular the resemblance to the apocrine glands of the axilla is of significance in the derivation of the breast.

The first indication of the development of the breast is the appearance of the milk ridge—a bilateral thickening of the epidermis extending from the anterior fold of the axilla downward on the ventral surface of the thorax and abdomen as far as the groin. This is largely a proliferation of the cells of the conum which undergoes a process of nodulation indicating the future areolas of the breast. In certain of the *mammalia* these nodosities are multiple but in man a single one occurs on each side in the thoracic region; the remainder of the areolage disappearing. The epithelial thickening which makes up the nodule dips into the tissues beneath the skin and at about the eighth month of fetal life undergoes a central necrosis thus establishing the lumina of the milk duct. At birth the nipple is not usually present but the mouths of the primitive ducts are seen in a dimple or cleft which is extruded to form an elementary nipple during the first month of life.

The nipple and primary ducts remain in this phase vital under hormonal stimulation; the process of sexual differentiation is accomplished in adolescence. Even then the growth of the breast is largely a secondary sexual characteristic for although the ducts develop proportionately the bulk of the breast is made up of fat and fibrous tissue. The formation of areola and the conversion of the breast into a secretory organ await for the most part the hormonal stimulation associated with the processes of reproduction.

Gross Anatomy.—The breast of the adult male unaffected by the secondary sexual differentiation remains as a vestigial structure and is of little significance. On the other hand the female breast is a highly differentiated organ and its anatomy is of great importance. Its general appearance and location scarcely need description but its intrinsic structure and its relationship to a joining tissues must be further considered. It lies slung between the deep and superficial fascia and the fibrous septa traversing the gland between these two layers are known as Cooper's ligaments. They not only serve to divide the breast into lobes or compartments but, inasmuch as the superficial layer of fascia is intimately attached to the skin over-

lying the breast, they also localize and guide disease processes in such a fashion that the changes in the skin are often of the greatest significance. Moreover the nervous, vascular and most important of all lymphatic distributions of the breast follow these fascial planes while the specific secretory components of the breast lie enclosed within these compartments. The pectoral fascia is a rather dense connective tissue structure overlying the muscular and bony components of the thoracic walls and contiguous with the similar layer beyond the site of the breast. It serves as a limiting membrane between the breast and the underlying structures but is penetrated by and carries with it various contributory structures to the breast notably the lymphatic apparatus. The drainage from this is for the most part through the nodes in the axilla, although flow to the lymph vessels within the thorax and in fact in all directions is not inconsiderable.

Microscopic Anatomy.—Finer observation of the breast shows it to be an alveolar gland made up of 15 or 20 lobes each with its duct enlarging into a lacuna as it approaches the nipple and opening at the apex of these structures by multiple pores. The main ducts in the nipple are lined with a squamous type of epithelium which passes over as one follows through deeper into that of a cylindrical type until when the acini are reached a more cuboidal epithelium is found lying in two layers. These are seated on a *membrana propria* and surrounded by connective tissue related more closely to the epithelial structures than to the supporting fibrous framework.

Anatomical Variations.—The anatomical variations are those of deficiency or excess and may include the breast or nipple either alone or combined.

Complete absence of the breast and nipple is a rare condition frequently associated with an agenesis of the pectoral muscles. In those unusual persons with a developmental lack of sweat glands, the breasts may likewise be absent. Rarely, the breast may be present without any suggestion of a nipple although a retarded or imperfect development of the latter is fairly common. Such congenital variations in the size and form of the nipple are the flat bivalvular or split and the buried nipple. These are of significance only as they interfere with nursing or lead to confusion in the diagnosis of acquired disease.

Accessory Breast.—The accessory, fully developed breast with nipple which is capable of lactation is well known and forms a

chapter in all collections of medical curiosities. This anomaly may be multiple with a series of breasts as in the sow but is more customarily a bilateral accessory breast just above or below the normal one. Whenever it is present with but the rarest exception it is located along the embryonic milk ridge. Much more frequent indeed a common anomaly if looked for is the accessory nipple unaccompanied by any discernible breast tissue and many times scarcely more than a small thickened and pigmented area in the skin. These variations are of no significance other than psychic but this in itself may justify removal. There is no evidence that the supernumerary breast is any more likely to be the site of neoplasm than is the usual form.

The *aberrant breast* is a somewhat different matter. It occurs in the axilla usually directly contiguous to the upper and outer margin of the normal breast and on cursory examination may be readily mistaken for a lipoma. It is more commonly discovered at lactation when it responds as does the normally placed organ. It seems although this is a matter of clinical impression rather than of statistical evidence particularly liable to carcinoma and on the slightest suspicion should be removed.

Another type of aberrant mammary tissue which closely associates the breast with the sweat gland is the *cutaneous gland of the axilla*. This apparently a differentiation from the apocrine glands present there responds by proliferation and secretion at the onset of lactation continues in this state for about a week and in another week is again quiescent.

Functional Variations—The functional variations of the breast may be divided roughly into three categories the boundaries of which are not sharply defined and which at times may occur more or less simultaneously. These are the growth of the breast accompanying the development of secondary sexual characteristics the changes involved in the menstrual cycle and the mobilization for lactation. All three of these activities are determined by hormonal stimulation or perhaps by a shift in hormonal balance the pituitary and the ovarian or testicular hormones being chiefly concerned.

The structures in the breast which are

played on by these hormones are the epithelium of the ducts and acini and no less important, the periductal and periacinar connective tissue.

The differentiation of the female breast is accomplished as far as mass is concerned largely by an increase of fat and supporting fibrous tissue for which internal secretions of the anterior pituitary are responsible. To this must be added however an increase in the branching and length of the ducts and a striking proliferation in the periductal connective tissue so that the breast becomes skeletonized as it were for its future function of lactation. This phase of the growth

Fig. 459—The "milk line" along which accessory breasts and nipples occur (Merkel Topographical Anatomie)

is probably induced by the estrogenic substance.

With the establishment of menstruation a rhythmic change occurs in the breast as is the case with the endometrium and probably as a result of the same hormones. The precise details of this are not well known but in many instances there is subjective discomfort a sense of fullness at or just antedating menstruation and in some instances a slight discharge from the nipple. Rarely this may be bloody the so-called *menstruous menstruation* although it is far safer to assume that such a discharge arises from a ductal papilloma. Histologically the acti-

vation is marked by a proliferation of ductal epithelium and of the periductal connective tissue and with the passing of the estrus these return to a resting phase. When this periodic stimulation comes to an end with the menopause the specific structures of the breast undergo a fairly complete involution so that nothing remains but the dilated ducts, a minimum of periductal tissue and an atrophic supporting structure making up the senile breast.

When the ovum is fertilized and becomes implanted the breast continues on into a development preparatory for lactation. The ducts branch and extend more deeply and at their terminations acini develop while the periductal and pericinar connective tissues undergo marked hyperplasia. The breast increases in size as a result of these activities, becomes more vascular and with the termination of the pregnancy under the influence of an anterior pituitary hormone (prolactin) starts producing milk. With the cessation of nursing the gland undergoes involution to a resting stage and with the recurrence of the estrus cycle again takes up its menstrual rhythm.

Functional Aberrations—Directly after birth the breast of the infant shows rapid growth with extrusion of the nipple and it is not at all uncommon probably under the influence of the prolactin of the mother for the breast in a few days to secrete a small amount of so called 'witches' milk'. This turgidity of the breast and discharge are sometimes mistaken for infection but this is rarely the case and with the passage of a few days the phenomenon subsides.

Likewise at the time of puberty fullness of the breast and the presence of small amounts of milk are occasionally noted. This condition may be observed in the male or female. This is again probably the result of a disturbance of the balance between estrogenic substance and prolactin.

In the male the enlargement of the breast may persist or even increase a condition called *gynecomastia*. It is discovered at all ages but not rarely in routine examinations of male students of the college age. It is usually bilateral but to some degree may be unilateral. There is frequently discomfort or even sticking painful sensations. On inspection a miniature breast and nipple are

apparent and a small elastic disk of breast tissue may be felt. Microscopic examination shows ductal but not acinar proliferation and increase of periductal fibrous tissue. Occasionally there are small cysts and the whole appearance resembles in a minor degree cystic disease of the breast of the female. At other times the appearance is that of the normal breast of the female child. Gynecomastia is occasionally associated with anomalies of the genital apparatus or endocrine disorders. There is no correlation of this condition with malignant disease.

In the female a continued stimulation by estrogenic substance of the growth of the breasts leads at times to 'virginal hypertrophy' which in extreme instances forms one of the curiosities of growth. The breasts may be truly enormous so much so as to be not only a source of embarrassment to the patient but an actual physical handicap. This aberration usually involves both breasts and in fact unilateral hypertrophy should lead one to suspect a massive lipoma or fibroadenoma of the breast.

Microscopic examination shows a true hypertrophy of the breast with the periductal fibrous hyperplasia predominating and the ducts themselves being relatively inconspicuous. There is a high incidence of fibroadenoma in virginal hypertrophy and growth is particularly rapid at puberty and during pregnancy. As has been pointed out recently there is considerable probability that gynecomastia, virginal hypertrophy and fibroadenoma are the result of excessive hormonal stimulation of the same type the estrogenic substance that is concerned with the normal growth and differentiation of the breast.

Disturbances of Circulation and Innervation—Very rarely does spontaneous *hemorrhage into the breast* occur and then in conjunction with the usually hyperemic breast of menstruation or of lactation. Much more common is bleeding from a cyst already present caused by a papilloma or trauma. A localized injury may lead to hemorrhage into the breast and fat necrosis. The immediate result is frequently overlooked and the patient complains of a lump in the breast. It is exceedingly difficult if not impossible to distinguish this from carcinoma short of a biopsy and this should be done.

While massive necrosis or gangrene of the breast has occurred as a result of a generalized streptococcal infection unfortunately the most common cause is that of hypodermoclysis of a physiologic or hypertonic saline solution directly into the breast. Under these circumstances the fibrous ligaments of the organ serve to confine the fluid until the pressure is sufficient to obliterate the arterial supply and a massive necrosis occurs.

Disturbance of the innervation is confined to neuralgia of the breast, more commonly called mastodynia. While this may be a true disease of the nerves supplying sensation to the breast or even an hysterical manifestation it is always much safer to avoid such diagnoses and search for an organic lesion. This will usually prove to be a cystic disease of the breast in which pain and discomfort are frequent symptoms.

Inflammatory Diseases of the Breast—A common and painful affection of the nipple is the fissure which arises as a result of nursing. This is not only important from the discomfort involved and the interference with suckling but frequently acts as a portal of entry for pyogenic organisms thus leading to abscess of the breast. The best prevention is cleanliness before and during lactation and this is best achieved by washing with sterile water and painting with a dilute compound tincture of benzoin. The use of strong antiseptics only leads to further drainage and when the discomfort is great an artificial nipple may be used or in the extreme instance nursing abandoned and the breast pump substituted for it. An ulceration of the nipple should suggest at once either carcinoma or the primary sore of syphilis.

The areola is an area in which the skin is thin as parchment unattached to the underlying superficial fascia and contains the large sebaceous glands of Montgomery.

The areola is subject as is the skin of the nipple to what is commonly called eczema. This is not in any instance a sufficient diagnosis and all care must be exercised in arriving at the true etiology. Such is particularly the case in this region because eczema is not an uncommon manifestation of an underlying ductal carcinoma, the so-called Piget's disease (see section on Piget's Disease). In other instances the causative

agent quite unsuspected and not obvious is the itch mite of scabies and the pruritus and scratching may lead to infection resulting in an abscess lying between the skin of the areola and the superficial fascia. Such a localized infection may also arise from infection of the glands of Montgomery. Lastly similar excoriation and infection may lead to an impetiginous eczema which may spread over the skin of the entire breast. Another and very common cutaneous lesion is associated with the breast, the intertrigo which occurs in the fold beneath the pendulous breast particularly in a patient who is not scrupulously clean.

Fig. 44—The location of breast abscesses: a Subareolar abscess; b areolar abscess; c intertrigo; d axillary abscess; d intra areolar abscess (After Klose.)

It is not at all uncommon in the first few days of onset of lactation or at other times when the breast is not adequately emptied for caking to occur. A segment or even a major portion of the breast becomes thick, painful and tender and on palpation feels dense and warm as compared with the surrounding tissues. There may be some fever and leukocytosis and the possibility of a developing abscess is at once suggested. The mechanism is that of a stasis and curdling of the milk within the lobules of the breast and a mild inflammatory reaction. With gentle application of the breast pump support of the breast with a firm binder and icebags for comfort the condition usually recedes.

and there is no impairment of the lactational function of the breast

This condition is to be differentiated from abscess of the breast, which usually starts somewhat later, i. e. toward the second month of nursing and is the result of a pyogenic infection most frequently staphylococcal through the lymphatics from a fissured or excoriated nipple. At times this infection is imposed on a stagnation of milk and the differential diagnosis is difficult. Pyogenic infection is indicated by a marked accentuation of the milder symptoms. The breast or a sector of it is tense, extremely tender and painful and quite hard to the touch until such time as suppuration leads to fluctuation, a late phenomenon. The systemic reaction is much sharper often starting with a chill and with a rise in temperature to 104° or 105° F. Leukocytosis is marked with the segmented forms predominant. The final differential diagnosis must wait on localization of the process with redness and edema of the overlying skin and even fluctuation. In some respects the process resembles a carbuncle of the neck in that the infection is first confined within the lobular fibrous compartments of the breast from which it may reach the skin or if more deeply seated may penetrate into other compartments and thus involve a major portion of the breast before fluctuation is detectable. Therefore fluctuation must be diligently sought for and drainage established at once when it can be found.

For this purpose it is important to make radial incisions outside the areolar region in order to avoid dividing the larger ducts and possibly causing a milk fistula. It is equally important to drain the region thoroughly with all liquefied areas opened up in such a fashion as to obtain dependent drainage. A through and through rubber-covered drain from outside the areola traversing the abscess radially and emerging at the outer margin of the breast accomplishes the most with the least damage. It is necessary to stop nursing entirely even with the unaffected breast for the act of sucking would stimulate the flow of milk in the diseased breast also. The breast pump should be gently used to remove the excess milk. The breasts should be firmly supported and an icebag used.

"Chronic Cystic Mastitis"—It is customary to consider under the chronic inflammatory diseases of the breast a condition which although clinically and pathologically definite as far as its etiology and its relation to malignant disease are concerned has been and still is the subject of controversy. It was first recognized as an entity by Sir Astley Cooper but the notable studies of Reclus and Schimmelbusch focused attention on the condition. Unfortunately almost without exception each investigator devised a new name which serves rather to confuse than to clarify the situation. Probably the term 'cystic disease of the breast' is sufficiently inclusive and non-committal to represent the state of knowledge concerning the condition.

The more recent studies concerning the influence of the hormones on the growth and function of the breast have been considered briefly. That they have some bearing on the etiology of this disease can no longer be questioned but the details of this action are open to further elucidation. Quite aside from such hormonal interpretation it is known that the breast concomitantly with the estrus cycle undergoes stimulation and regression. This is shown histologically by hyperplasia of the periductal fibrous elements and the epithelium of the ducts with budling and branching which if fertilization and implantation of the ovum occur continues during pregnancy until lactation supervenes at birth. With the completion of menstruation the breast like the endometrium undergoes involution and returns to a resting stage. It requires no considerable imagination to conceive of this process as becoming exaggerated and unbalanced as happens in the case of the endometrium leading to greater than normal activity of either the fibrous or the epithelial hyperplasia or both and likewise incomplete involution from either the normal or the exaggerated response. In any case there may well result a fibrous overgrowth or an epithelial overgrowth or a combination of both. The generalized overgrowth of the periductal fibrous tissue has been discussed under vaginal hypertrophy and the localized overgrowth resembles at least that seen in fibroadenoma. Likewise the epithelial hyperplasia within the membrane propria surrounding the ducts may be general

ized or localized and may result in adenomatous collections of cells increase in ducts and acini and the formation of cysts of varying size. When the disturbance of the normal process includes as it usually does both the fibrous and epithelial elements the picture becomes extremely variegated and it is not at all surprising that confusion of description and interpretation results.

In the recognition of this disease the subjective findings are much more prominent than they are in malignant disease of the breast. There is commonly a sticking pain

but on examination one usually finds other evidences of disease. Frequently there are other smaller nodules but they may be grouped together in one area so that there seems to be a mass surrounded by induration closely simulating carcinoma. Fortunately palpation of the entire breast more often reveals multiple nodules of varying size or gives a shotty feel or beneath the areola there is the sensation of palpating a clump of worms. Again the breast can be picked up as a thickened and resilient disk, the so-called saucer breast. Examination of

Fig. 153.—Hyperplasia, hypermaturation, desquamation and cyst formation occurring in the duct epithelium of the breast in cystic disease. (After Cheate and Cutler.)

often referred to the shoulder or to the inside of the upper arm. It is obviously a referred type of pain and is rarely severe, very characteristic is its increase at about the time of menstruation, the breasts at the same time becoming tender. Visual inspection rarely indicates any abnormality although a single large cyst may at times cause obvious deformity.

Palpation usually reveals a greater degree of tenderness than accompanies other tumors of the breast. There is no intimate attachment to the skin and the breast itself is not fixed to the underlying tissues. The patient frequently complains of a single lump

the opposite breast also reveals definite disease in the majority of instances.

The differential diagnosis is that from benign and most important of all malignant tumors. In the former case there is much less likelihood of multiplicity of lesions but the clinical distinction of a fibroadenoma from a single cyst is difficult. Transillumination should in theory pass through a cyst but not a solid tumor even as one would expect less resistance or even fluctuation in the cyst. In practice these distinctions are of little assistance except in tumors the size of a bird's egg or larger. The same is true also of examination by the soft roentgen ray.

At times the simple, obviously benign tumor may be aspirated with a fine needle in order to establish a preoperative diagnosis but inasmuch as such a tumor should be removed irrespective of the findings this maneuver is of but little practical value.

Much more important is the distinction of this disease from neoplasm particularly carcinoma. Involvement of the skin retraction of the nipple fixation of the breast and other similar signs are indicative of relatively advanced disease. Today more patients ask for advice when these characteristic signs are not present even in cancer and consequently while the differential diagnosis becomes more difficult the responsibility of the surgeon at the same time becomes greatest. When there is a single dense nodule in the breast irrespective of what may be present otherwise the diagnosis of non malignant disease can not be made short of an exploration of the lesion. Where no nodule is present and both breasts are involved to some degree in uniform disease the diagnosis of benign disease may be made with a considerable degree of safety.

The course of chronic cystic mastitis is a slowly progressive one with little disability aside from that of a subjective nature. With the climacteric and the onset of senile involution the process subsides or remains quiescent. While the incidence of cancer in the breast so involved is somewhat higher than that in the corresponding age groups this difference is not sufficient to justify ablation on this basis alone. However it is of the greatest importance that early carcinoma in the breast involved in a "chronic cystic mastitis" is difficult to discover and still more difficult to rule out. Therefore it is necessary to watch such breasts with greatest care and at the slightest suspicion to proceed at once in establishing the diagnosis by exploration.

Were this possibility of confusion not present in many instances the surgeon would adopt an expectant attitude. As the situation frequently occurs he will feel called on to carry out an operative procedure. In certain instances particularly in middle aged patients a conservative mastectomy is indicated but even this causes a mutilation to be avoided if possible. Frequently the local resection of a quadrant of

the breast which is most intensively diseased will settle the question of cancer in that area and where there is a discrete movable nodule the removal of this will determine its character at once. Certain it is however that the surgeon who carries out any of these procedures with the primary aim of ruling out cancer must be a competent gross pathologist who can diagnose the lesion at first hand with a reasonable degree of certainty. Likewise he should be sufficiently familiar with the microscopic appearance in the frozen section which should always be available so that he in consultation with the pathologist may arrive at once at a decision as to whether or not a radical attack for cancer is necessitated.

TUMORS OF THE BREAST

The mammae are modified cutaneous glands. In the male they atrophy after birth. In the female they are "dormant" until puberty when they hypertrophy but attain full functional development only at the end of pregnancy to fulfill their prime function—lactation. Regression occurs after weaning but never to the state existing prior to pregnancy. Definite cycles of proliferation and regression take place with each menstrual cycle, owing to hormonal influences especially from the pituitary and ovaries. Atrophy ensues after the menopause.

In a full female the breast tissue proper is in the form of a disc surrounded by fibroadipose tissue. Its most superficial portions are beneath the areolae pigmented circular areas in the center of which is the nipple. Fifteen to twenty lactiferous ducts terminate in the nipple each with its own orifice. Each lactiferous duct corresponds to a lobule of breast tissue; these are arranged radially about the nipple. The lactiferous

ducts are continuous with smaller ducts which subdivide repeatedly forming fine tubules. The latter end finally in sacs or acini. In lactation the cells of the acini undergo transformation into milk-secreting cells. The connective tissue immediately surrounding the smaller canaliculi and acini is loose and relatively cellular. It responds to hormonal influences as does the breast epithelium and undergoes changes concomitantly with the latter. The size and contour of the breast and the quantity of breast tissue proper vary widely and differently and vary duals corresponding to the general constitutional type.

Examination of the Patient—When the female breast is examined for neoplasm a definite routine should be followed. The physician should never be satisfied with rapid cursory haphazard palpation. Complete exposure of both breasts is necessary. Each breast is first inspected while the patient is sitting upright or standing. Attention is focused upon the general contour and appearance of the skin and nipple. Search is made for localized bulges or depressions. The relative size of each breast is noted. Palpation is carried out by gentle grasping of different portions. The patient is then requested to lie down upon her back and inspection again carried out. The arm is fully abducted so that it is parallel to the side of the head with the forearm horizontal over the top of the head. Palpation is carried out with the flattened hand pressing the breast against the ribs and moving it backward and forward. Palpation in a similar manner is carried out upon the terminal portions of the pectoralis major muscle which form the anterior axillary fold. Palpation of the floor of the axilla is carried out by pressure of the fingers directed against the mesial wall of the axilla (ribs) and then forward onto the under surface of the terminal portion of the pectoralis major muscle and toward the apex of the axilla. Finally the hand is cupped about the breast with moderate compression in order to ascertain whether or not any discharges can be expressed from the nipple.

The female breast is a common site of neoplasms both benign and malignant. While the breast includes the skin and its appendages and fatty and fibrous tissue and therefore may exhibit tumors of these tissues only those tumors peculiar to the mammary gland proper will be considered here. These may be classified as follows:

Benign

- I Fibroadenoma
- II Pericanalicular fibroadenoma
- III Intracanalicular fibroadenoma
- IV Adenoma
- V Intracanalicular papilloma
- VI Cystosarcoma phyllodes

Malignant

- I Carcinoma
- II Paget's carcinoma
- III Sarcoma

BENIGN TUMORS OF THE BREAST

Fibroadenoma, Pericanalicular Fibroadenoma and Intracanalicular Fibroadenoma—Clinically these benign tumors may be considered together. They are ob-

Fig. 450.—A benign tumor of the breast in the case of an intracanalicular fibroadenoma. The granular appearance of the cut surface is due to small intracanalicular papillary projections. Note the color of the tumor in contrast to the normal breast tissue between divided halves.

served in females most frequently between the ages of twenty and forty-five. The tumor is usually not painful or tender on palpation although pain and tenderness may on occasion be present and often is referred to the shoulder axilla or arm especially in the immediate premenstrual period. The common sites are in the breast beyond the areolae. The tumor is usually on the superficial aspect of the disc of breast tissue and produces a circumscribed bulge but it may also be deeply embedded. On palpation it is quite firm may exhibit a stiff elasticity, appears to be well encapsulated and seems quite mobile on the surrounding tissue especially when it is superficial. When a finger is pressed downward upon the tumor it

readily moves in one direction or the other. When grasped between the thumb and index finger it may readily slip away from between these digits. If the growth is deeply embedded in the breast, its motility is often quite limited and in some instances affords the impression of an infiltrating process. These tumors are usually single but may be

firm whitish rounded or oval masses sometimes with rounded bulges on one or several aspects (Fig. 457). Because of their color and density they contrast rather sharply with the surrounding grayer, softer breast tissue. They are easily enucleated from the latter. The fresh surfaces of the intracanalicular fibroadenoma exhibit small

Fig. 457—Histologic appearance of various benign breast tumors $\times 50$. *A* Fibroadenoma. Ducts and stroma have proliferated, cystic dilatation of the ducts. Proliferation of stroma. Canals show little cystic dilatation. *B* Pericanalicular fibroadenoma. Relatively greater proliferation of stroma. Canals show little cystic dilatation. *C* Intracanalicular fibroadenoma. Characteristic configurations of intracanalicular processes. *D* True adenoma. Proliferation of ducts and acini with no proliferation of stroma. Large duct in center of section.

multiple in one or both breasts, the latter condition however is not common. When first seen the growth varies from 1 to 3 cm in diameter but on rare occasions may be considerably larger. Growth is slow and upon attaining 2 to 3 cm in diameter the tumor may appear to remain stationary for varying periods. Patients may be under the impression that they vary in size.

Pathology—Macroscopically they are

raised nodulosities due to the intracanalicular processes.

The histologic characteristics are as follows (Fig. 457).

A FIBROADENOMAS—Both the periductal connective tissue and the duct epithelium have proliferated. The ducts appear numerous, slightly to moderately dilated and more or less uniformly distributed in the loose stroma.

B PERICANALICULAR FIBROADENOMA.—The periductal and periacinous connective tissue appears to have proliferated more extensively than the epithelial elements. Individual canaliculi or small groups of these are surrounded by relatively wide zones of stroma.

C. INTRACANALICULAR FIBROADENOMA.—There has been relatively greater proliferation of connective tissue than of epithelial structures, and the former has pushed into the canaliculi, forming coarse indentations leading to dilatation of the canaliculi and almost complete obliteration of their lumina. Characteristic configurations are produced.

Some neoplasms may exhibit, in different areas, combinations of two or even all three of these histologic characteristics.

Treatment.—The final diagnosis of any breast tumor cannot be made without histologic study. Therefore, if this is desired, excision (which in these growths is just as easily performed as biopsy) is indicated. Indeed, with the extensive anticancer propaganda among the laity in the past years, most patients readily accede to removal of a breast tumor when this is a minor procedure and will afford final confirmation of benignity. On the other hand, in the presence of all the clinical signs that have been enumerated, it can hardly be stated that excision of these tumors is mandatory. Transformation of them into carcinoma or sarcoma is so rare, if it ever does occur, that excision cannot be justified on the basis of ablation of a precancerous lesion. Another reason for their removal is their progressive increase in size. Neoplasms that are tender or the cause of spontaneous pain should be removed. When the neoplasm is resected, recurrences usually do not occur if excision has been complete. However, similar growths may appear later in the same breast near the site of the original growth or in the opposite breast.

True Adenoma.—This is a rare tumor. It is composed of numerous, closely applied ducts, canaliculi and acini, with relatively little stroma. These growths vary in size and may be quite firm or soft and fleshy. Some of the recorded instances of true adenoma may in reality represent localized areas of hypertrophy rather than true neoplasms, in that they were observed during pregnancy

and histologically resemble normal breast tissue evolving toward the stage of lactation (Fig. 457, D). The nature of the tumor is appreciated only after excision and microscopic examination.

Intraductal Papilloma.—Two types of intraductal papilloma occur—the single lesion and multiple growths. The solitary papilloma usually develops in or near the dilated (ampulla) portion of the terminal segment of the lactiferous duct. It consists of a single basal stalk of attachment from which numerous villous processes arise, the whole forming a rather complex structure

Fig. 458.—Cross appearance of large intraductal papilloma in terminal portion of lactiferous duct. The nipple is on the opposite side of the specimen just over the depicted lesion.

(Figs. 458, 459). These growths are covered with low to tall columnar epithelium. When the lesions are multiple they may arise from the smaller as well as the larger ducts and cause dilatation of them in the regions of their growth. A striking situation is the occurrence of multiple lesions confined to one large duct and its tributaries, whereas ducts of adjacent lobes are free from the lesions. Where the papillomas are multiple and situated close to one another, their distal portions may fuse, with formation of a complex intraductal lesion with multiple stalks of attachment (multiradicular growths).

Signs and Symptoms.—Intraductal papil-

lomas are observed most frequently in women between thirty five and fifty five years of age. The characteristic sign is a spontaneous hemorrhagic discharge from the nipple. When the breast is compressed a drop of the discharge forms on the nipple and resembles the drop of blood resulting from the prick of a sharp instrument on the finger or lobule of the ear as obtained for blood counts (Fig. 460). Less frequently the discharge is essentially serous with traces of blood or it may not be hemorrhagic at all. The papilloma may be palpable as a rounded somewhat elastic nodule usually beneath

are benign but there is good evidence that they may undergo malignant degeneration. No information is available to indicate how long they may remain benign before undergoing malignant changes although they have been observed to remain benign for prolonged periods. Spontaneous disappearance of the growths has also been reported but this is of such rarity that it should not be considered in connection with treatment.

Treatment—When the diagnosis is made excision is indicated because of their possible precancerous nature. Single papillomas are excised locally with surrounding tissue. When

FIG. 460—Intraductal papilloma of the breast. $\times 20$.

the nipple or areola. Multiple lesions may be palpated as small nodules in these areas and also farther out in the breast away from the areola. In unusual instances they form masses larger than 1 cm. in diameter. On the other hand the tumors may not be palpable at all because of small size and yet the hemorrhagic discharge from the nipple is regularly present. Intraductal papilloma is in most instances confined to one breast but rarely may be present in both breasts. The single lesion is not painful or tender to palpation; some discomfort may be associated with multiple papillomas.

It is generally stated that these lesions

they are multiple excision should be wide enough to encompass all of the lesions. Recurrences may develop indicating incomplete removal of the original growths or development of new lesions in other ducts.

'Cystosarcoma Phylloides'—Although the term cystosarcoma phylloides suggests a malignant neoplasm these growths are benign. They are not very common and are usually observed in women between forty five and fifty five years of age. They are not uncommonly observed in younger subjects. They are characterized by the formation of a very large mass that greatly distorts the breast. On palpation the tumor is

a precancerous condition although certain forms in which considerable intraductal proliferation of cells (adenosis) is present may prove to be evidence of the activity of carcinogenic factors as yet unidentified

Over the years considerable experimental work has been carried out in breast cancer

Fig. 461—Section through the breast of forty-two year old woman showing numerous scattered small cysts and a recently biopsied carcinoma (T) Two years previously a large cyst in reg. on C was aspirated of yellow cloudy fluid. No gross evidence of the cyst is present in the specimen

in mice. There are strains in which the females have a high incidence of breast cancer and strains of low or no incidence of this tumor. Oophorectomy in early life prevents normal maturation of the breast and in such rudimentary glands carcinoma does not develop even though the animals are

of the high incidence strain. Large doses of estrogens have hastened the development of breast cancer in susceptible females and even led to its development in males of the high incidence strain. A factor in the milk of high incidence strain has recently been discovered by Bittner which plays an important role in the development of breast cancer in mice. If the newborn mice of a high incidence strain female are immediately removed from the mother and suckled by a low incidence strain female the incidence of breast cancer in the females will be appreciably reduced. If the young of low incidence strain are suckled by a lactating female of high incidence strain the number of carcinomas of the breast in the females will be appreciably increased. The milk factor is not the only influence however since in hereditary predisposition to breast cancer also obtains

Pathology.—Carcinoma may arise in any portion of the breast but seems to be more common in the upper outer quadrant. The growth is highly infiltrative and spreads by direct extension within the ducts infiltration of the surrounding fatty tissue and permeation of the lymphatics. Macroscopically the tumor tissue is dull gray and often semicartilaginous in appearance and consistency. The cut surfaces are smooth and mottled gray and yellow. Small cystic spaces with brownish or hemorrhagic fluid may be present or they may contain sebaceous like material. Infiltration of the lymphatics and areolar tissues gives rise to an inflammatory reaction which results in contraction of the tissues toward the growth. The terms scirrhous and medullary as applied to carcinomas of the breast have come down from the older literature and are gross descriptions signifying the firm and more fleshy varieties of the neoplasms respectively.

There is a wide variety of histologic types which will not be discussed in detail here. They correspond roughly to the gross scirrhous or medullary forms (Fig. 462) in that the former is characterized by infiltration of tubules and cords of malignant cells surrounded by a dense fibrous tissue reaction and the latter by large irregular masses of epithelial cells with relatively little stroma and less fibrous tissue proliferation.

Metastases from carcinoma of the breast

may occur early in the course of development or may not take place until the process has become well advanced locally. In young subjects metastases occur earlier and are more widespread than in older patients. They are both lymphogenous and hematogenous. The first metastases are lymphogenous and are usually to the axillary lymph nodes, the infraclavicular and supraclavicular nodes are subsequently involved. However, where the process arises deeply within the breast and near the pectoral muscle spread into the lymphatics of the chest wall and via these to the subpleural spaces, mediastinum and even into the abdominal subperitoneal space and abdominal viscera may occur. The latter types of metastases

lymphogenous spread rather than by hematogenous dissemination which is the usual pathway for this type of metastases.

Diagnosis—The typical well established carcinoma of the breast presents such characteristic features that the clinical findings suffice for diagnosis (Fig. 463) yet final confirmation by histologic examination should always be made. Aspiration biopsy by means of the proper sized needle or special devices has gained favor in some quarters and in expert hands appears to be satisfactory especially when the findings are positive. In the face of suggestive clinical evidence for carcinoma negative aspiration biopsies should not be accepted as final. A good practice is to prepare the patient for radical op-

A

B

may develop extensively before there is appreciable invasion of the axillary lymph nodes. From the mediastinal lymphatics spread may occur into the thoracic duct and via this channel into the left jugular and subclavian veins. On the other hand permeation into the blood vascular system also takes place at the primary site and by this route metastases are carried into the lungs, liver, brain and elsewhere. Metastases from carcinoma of the breast are frequently present in the skeleton and they may extensively involve the osseous system while visceral metastases are few or not present at all. Diffuse skeletal involvement of the regions adjacent to the affected breast has sometimes been attributed to direct massive

invasion. In performing biopsy by incision into the suspected mass obtain an adequate block of tissue or preferably excise the entire mass for frozen section and then close the wound. New instruments, new gloves and possibly new drape and gowns are obtained while the histologic study is in progress. If the report is positive appropriate treatment then follows immediately.

As stated previously when the clinical signs of breast cancer are obvious the outlook for the patient is guarded. The prognosis is much brighter following proper treatment when the clinical diagnosis is of a small lesion is questionable and reliance upon biopsy findings is necessary for final diagnosis.

The clinical signs and symptoms include the following:

1 Lump in the Breast A lump in the breast is by far the most important finding in cancer of the breast. Its discovery is particularly important for the early diagnosis. The history given by the patient that the lump was accidentally discovered is a characteristic feature of the clinical aspects of breast cancer. In the early stages the malignant growth is not painful or tender. The tumor is quite firm and because of its infiltrative growth the outlines are indefinite. There is no enlargement and the breast

3 Retraction of the Nipple Where the neoplasm is situated beneath the nipple or near it beneath the areola, retraction of the nipple occurs as a result of infiltration of the subcutaneous lymphatics and lactiferous ducts by the growth. Retraction of the nipple may be sufficiently pronounced to afford the appearance of elevation of the most pendulous portions of the breast. This elevation is more easily appreciated when comparison of the contour of the affected breast is made with the unaffected opposite breast.

4 Orange Peel or Pigskin Appearance of the Overlying Skin When the subcutane-

FIG. 463.—Sixty-five year old patient with classical signs of well advanced carcinoma of the right breast. The involved breast is elevated, the nipple is retracted and there are two well marked areas of dimpling of the skin above and lateral to the areola.

tissue immediately surrounding it moves with the tumor in contrast to the mobility of certain benign tumors in the surrounding tissue.

2 Dimpling of the Overlying Skin When the growth is present in the superficial aspects of the breast and permeates the lymphatics which communicate with those immediately beneath the skin, the latter is drawn downward toward the growth, producing a characteristic depression or dimpling. This may not be readily apparent on simple inspection, but if an attempt is made to move the lump the skin will be drawn with it and the dimpling thus accentuated.

ous lymphatics are occluded by tumor cells with blockage of lymph flow in the area, the skin between the pores becomes puffy, accentuating the size of each pore. This gives rise to the appearance of orange peel or pigskin.

5 Flexion of the Breast The involved breast may appear retracted onto the chest wall and the nipple distinctly elevated as compared to the opposite breast. This condition is encountered where the carcinoma has invaded most of the disc of breast tissue and has become attached to the pectoral fascia, producing general contraction of the surrounding connective tissue.

6 Discharge from the Nipple This is in constant and has little diagnostic significance, because certain forms of cystic disease, infectious lesions and intraductal papillomas may produce discharges of various types from the nipples. Hemorrhagic discharges may, however, be present in cancer.

7 Palpable Lymphadenopathy in the Corresponding Axilla. The presence of firm nodules in the axilla indicates metastases to the axillary lymphatic nodes. Absence of these nodules does not preclude metastases since the adipose tissue may mask their presence.

indeed an acute carcinomatous cellulitis. Prognosis is extremely unfavorable.

3 Ulcerating Cancer of the Breast. While ulceration through the skin eventually occurs in many neglected cases late in the evolution of the disease, small lesions arising in the superficial portions of the breast may ulcerate relatively early, especially in elderly patients while the breast itself is not yet extensively involved. Prognosis can be estimated on the basis of axillary metastases in instances of early ulceration.

4 Cancer of the Breast in Pregnancy and Lactation. This situation has a grave prognosis. It is assumed that the physiologic factors inducing lactation operate to increase the rate of growth of the carcinoma. On the other hand the patients are usually young and rapid growth of carcinoma is the rule in this group. Furthermore, because of pregnancy and lactation there

Fig. 461—Cancer en cuirasse with area of imminent ulceration above and medial to the areola. The involved breast is converted into a firm, flattened disc contracted against the chest wall. This represents an advanced stage of the disease.

Special Clinical Forms of Carcinoma of the Breast

1 "Cancer en cuirasse" (Fig. 461). Extensive local infiltration with fibrosis and lymphedema of the tissues results in dense firmness of the breast which is retracted against the chest wall. The infiltration may extend beyond the actual limits of the breast onto the chest wall surrounding it. The condition has been likened to a breast plate; hence the name. It represents an advanced stage of the disease.

2 Inflammatory Cancer. In some patients, usually young subjects, the process appears to grow rapidly and permeates the cutaneous lymphatics with spread over the skin of the breast, the skin of the axilla and the chest wall at some distance from the breast. The involved areas are erythematous and may be slightly raised. Reddened plaques may be present in the skin at some distance from the breast. The whole process resembles an acute cellulitis; hence the name. It is

is local congestion of blood vessels and lymphatics, and this in itself would favor metastases. Prolonged survival can hardly be envisaged in these patients, although in rare instances "cures" have been reported.

3 Bilateral Carcinoma of the Breast. Bilateral carcinoma may be present or one breast may be affected and resected with carcinoma developing later in the other. In the latter it usually appears in the sub-areolar portion and has been regarded as due to lymphatic metastases across the chest wall. However, an independent process developing as a result of strong carcinogenic factors in the patient is an equally plausible explanation. The prognosis depends upon the extent of spread of each lesion. Prolonged survivals have been observed following bilateral radical mastectomy for carcinoma.

6 Carcinoma in Aberrant Breast Tissue. Small foci of aberrant breast tissue, in reality independent super-

numerary breasts are not very infrequently present on the borders of the pectoral muscles forming the anter or all of the axilla or in the subcutaneous tissue of the floor of the axilla. Carcinoma with rather typical signs may on rare occasions develop in these rudimentary glands while the corresponding fully developed normal breast does not include a malignant tumor.

7 **Comedocarcinoma.** This form of breast cancer first recognized by Bloodgood is characterized by relatively slow growth, the formation of a rather lump-like mass with indefinite outlines and relatively late metastases. A serosanguineous discharge from the nipple frequently occurs. The cut surfaces exhibit numerous small plugs of sebaceous-like material. Histologically the rounded masses of malignant epithelial cells exhibit cores of amorphous material which represent degenerated tumor cells and which afford the numerous small sebaceous-like plugs seen macroscopically. In some instances of slowly growing comedocarcinoma whole masses of tumor cells appear to have undergone degeneration into amorphous material. Foreign body giant cells are mobilized to the periphery or invade the masses affording a picture not unlike that seen when a sebaceous cyst ruptures into the surrounding connective tissue. Comedocarcinoma has developed at the termination of pregnancy or during lactation and the prognosis even under these conditions is not very grave especially if metastases have not occurred.

Treatment.—The universally accepted treatment for carcinoma of the breast is radical mastectomy, the principle of which is resection *en masse* of the breast underlying pectoralis major and minor muscles and axillary contents. The fascia over the serratus anterior (medial axillary wall) and over the anterior border of the latissimus dorsi is also resected.

The steps in the operation may be briefly summarized as follows. The patient is given general anesthesia lying flat on the back with the arm abducted 90 degrees.

1 The incision (Halsted) begins over the insertion of the pectoral muscle on the humerus and curves upward and inward over the head of humerus downward on the anterior chest wall medial to the inner border of the breast then deflecting outward to a point beneath the midportion of the inferior border of the breast. Another incision is begun starting from a point on the first incision above the superior border of the breast and curving outward along the lateral border to meet the termination of the first incision below the breast. The incision on the anterior chest wall is then carried downward to the pectoral fascia. The other portions of the incision are carried well into the subcutaneous fat.

2 The fibers of the pectoralis major arising from the clavicle are separated by the scalpel handle from those arising from the anterior chest wall a digit is hooked beneath the insertion of the latter near the upper end of the humerus and the fibers are divided. The detached portion of the pectoralis major is then drawn downward and medially with division of vessels and nerves to its deep surface. The lateral border of the anterior axillary fascia is then incised over its entire length and elevated. This permits entrance into the axilla.

3 The insertion of the pectoralis minor upon the coracoid process of the scapula is transected and this muscle is also drawn medially and downward with the pectoralis major. The axillary contents en masse are liberated from the walls of the axilla and kept retracted firmly against the detached pectoral muscles. Vessels and nerves coursing downward from the large vessels and nerves in the apex of the axilla are divided.

4 The incision on the anterior chest wall is then carried through the pectoral muscle to the underlying ribs. The fascia over the anterior border of the latissimus dorsi muscle is dissected upward to come away with the axillary contents. The fascia over the medial wall of the axilla is likewise dissected to come away with axillary contents.

5 The attachments of the pectoral muscles to the ribs are divided and this finally permits removal of the breast, pectoral muscles, axillary contents and adherent fascial strips *en masse*.

6 Complete hemostasis is important.

7 A strip incision is made in the lower skin flap to permit insertion of a soft rubber drain into the axilla.

8 The line of closure of the wound should not cause a web to be formed on the anterior axillary fold as this would impair motion at the shoulder joint. The cicatrix should eventually lie on the chest wall itself (Fig 465).

Passive motions of the arm are carried out the day after operation and the patient is encouraged to perform active motion as soon as possible.

There is considerable variation in the details of this operation as performed by various surgeons. For example there are many types of incision such as an elliptical one

beginning over the anterior aspect of the shoulder, including the breast and ending over the insertion of the rectus abdominis muscle on the lower anterior chest wall; a circular incision about the breast, with an extension to permit axillary dissection, a long transverse incision to include the breast, etc. There are also various recommendations for undermining the skin to permit approximation in closure or the fashioning of large flaps to accomplish the same purpose. There is the question of how much skin should be removed, some claiming that this should be sufficiently wide that skin grafting is routinely necessary, while others

gross evidence of distant metastases but with local evidence of advanced disease simple or even radical mastectomy is justified for palliative purposes to avoid or remove local ulcerations and ablate the breast tumor. An attempt to select patients for radical mastectomy would, in the author's opinion, result in inadequate treatment in some instances, as experience has shown that not very infrequently survival in comfort is possible far beyond what might have been anticipated. On the other hand radical mastectomy is not justifiable in cases of inflammatory cancer if the incisions cannot encompass the growth or if the progress of

Fig. 465.—Photograph after radical mastectomy showing disposition of areola on chest wall to avoid a web in the anterior axillary fold that would impair motion at the shoulder joint.

maintain that it is necessary to remove only about 4 to 5 cm. of skin beyond the gross limits of the growth (including of course the areola and nipple).

As has been stated, radical mastectomy is recommended in all cases when the diagnosis is finally confirmed by microscopic section, if the incisions may encompass the growth and if there is no gross evidence of distant metastases. Preoperative roentgenographic examination of the chest to demonstrate the absence of pulmonary metastases is recommended as a routine procedure. Radical mastectomy is contraindicated if the latter are present. In patients without

the disease is obviously very rapid in the presence of distant metastases.

The mortality incident to radical mastectomy itself has been progressively reduced in the past few decades; at present it should not exceed 1 per cent among competent surgeons.

Prognosis.—Death from carcinoma of the breast results from widespread metastases which lead to exhaustion of the patient or which by virtue of causing marked general deterioration predispose to terminal pneumonia or general infections of other types. Skeletal metastases may result in serious pathologic fractures or by extensive re-

placement of hematopoietic marrow may cause severe and fatal anemia. Intracranial metastases may in themselves be the direct cause of fatality. Thus the prognosis depends upon whether the disease can be eradicated early in its evolution before distant metastases have occurred.

Untreated carcinoma of the breast is not a rapidly fatal process; it appears that the average length of life in the absence of treatment is about forty to forty-eight months from the time the neoplasm is first discovered.

The prognosis in an individual case depends upon the age, type of growth and stage at which operation is performed. In general, approximately 60 to 70 per cent of patients who do not have axillary metastases and do not show infiltration of the skin or invasion of the pectoral fascia will survive at least five years without clinical evidence of disease. If the skin or pectoral fascia is involved and there are no axillary metastases or these are limited, approximately 35 per cent may survive five years; if axillary metastases are extensive but there is no evidence of distant spread, the survival rate falls to about 15 per cent. (In order to gain a definite conception of prognosis, all the axillary nodes should be examined histologically. It is not sufficient to section one or two or the most suspicious nodes.)

Even though the patient survives five years without clinical evidence of active metastases, cure is still not assured, as progression of metastases may become manifested even after this period of arrested growth. Nothing is known of the factors which result in the inhibition of growth of metastases for prolonged periods.

It is not extremely rare to have a patient with metastases, especially where they are confined to the skeleton, survive for prolonged periods, even for several years, under palliative treatment by roentgenotherapy. Large doses of calcium gluconate may also contribute to palliation, especially relief of pain. A grave prognostic sign is local cutaneous recurrences in the area of operation. While these may for a time be the only evidence of recurrences, ultimate death from metastases is the rule, even though the general condition may appear excellent at

the time the recurrent nodules in the operative field are noted.

Castration in the Treatment of Carcinoma of the Breast—Since the breasts are stimulated by the internal secretions of the ovaries prior to the menopause, castration has been advocated sporadically for many years as an adjuvant in the treatment of carcinoma of the breast. The rationale being that malignant mammary gland cells might also be stimulated by ovarian secretion. Berton was probably the first to advocate surgical excision of the ovaries in women prior to the menopause who had advanced carcinoma of the breast. In recent years, ovarian function has been suppressed by x-radiation in these cases. The reported results have varied and individual instances have been cited as spectacular examples of the benefits of such treatment. It is, however, generally recognized that the benefit, if indeed they do occur, are temporary and that the patient eventually succumbs from carcinoma. In view of the fact that the question is still a moot one, after more than forty years, it would seem to the writer that little is to be expected from castration or a dry sterilization of these patients.

II PAGET'S DISEASE OF THE NIPPLE

Historical—Sir James Paget in 1847 first called attention to a clinical picture that has today become the subject of great controversy and much confusion. Paget originally described fifteen cases as follows: "Chronic affections of the skin of the nipple and areola

was succeeded by the formation of scirrhous cancer mammary gland'.¹ Although it is now known that the microscopic studies were made of Paget's not all were found to be cases of true Paget's nevertheless he was the first to call attention to the clinical and pathological condition of prime importance. The confusion concerning Paget's disease of the breast is due largely to the fact that Paget's careful descriptive clinical observations were misinterpreted

by microscopic study and descriptions. The fact that the surgeon, the dermatologist and the gynecologist all have different conceptions of the disease and McFarlan² state: 'But there is another source of confusion. To many surgeons Paget's disease is a clinical entity whose chief characterization is about the nipple and areola. In the preparation of this writing we carefully read the accounts of disease in twenty textbooks of surgery and

in the impulla of the terminal duct and that it spreads along the duct to the surface and to the deeper parts. It extends over the nipple and the areola and at times well out onto the integument of the breast. This new growth is composed of 'Paget's cells', and unless these cells are present one is not dealing with a true case of Paget's disease. These cells are characteristic. They begin in the malpighian layer and are peculiar large hyperchromatic cells with a decided malignant appearance. (2) Occurring deeper in the mammary substance is a carcinoma of a small duct. This has all the clinical significance of any other type of mammary cancer.

466—Showing Paget's disease of the nipple that began as a granular ulceration of the nipple slowly spreading onto the areola and out over the skin. At times the area is covered by a dry, scaly hard integument, at other times the entire area is moist. It has a mucoid secretion and bleeds easily.

was astonished to find that it was exceptional to find a correct or adequate statement regarding it. Most common mistakes were the statement that the disease was a squamous cell carcinoma of the nipple or that Paget's disease was the result of the invasion of the skin by carcinoma of the

Definition and Pathology—Paget's disease of the nipple to the best informed student of the subject signifies a complex clinical disease process. It represents two entirely different and entirely disconnected biologic processes occurring simultaneously in the mammary tissue and in its integument. (1) It is believed by some that the disease commences in the epithelial lining of the isthmus of one of the terminal ducts. Others maintain that it commences

in the impulla of the terminal duct and that it spreads along the duct to the surface and to the deeper parts. It extends over the nipple and the areola and at times well out onto the integument of the breast. This new growth is composed of 'Paget's cells', and unless these cells are present one is not dealing with a true case of Paget's disease. These cells are characteristic. They begin in the malpighian layer and are peculiar large hyperchromatic cells with a decided malignant appearance. (2) Occurring deeper in the mammary substance is a carcinoma of a small duct. This has all the clinical significance of any other type of mammary cancer. Handley,³ one of the greatest students of the subject maintains that Paget's disease commences primarily as a superficial carcinoma of a duct of the breast and that as it grows a disturbance is created in the lymphatics of and about the nipple and areola which in turn is responsible for the formation of the neoplastic cells of the integument. Cheatle⁴ maintains that in many instances there is no demonstrable connection between the deeper mammary carcinoma and the neoplasm of the skin. At any rate one thing of great practical importance must be kept in mind namely if biopsy of the skin of the areola or nipple shows Paget's cells there is always a deeper lying mammary tumor present even though the

chician cannot find it on palpation This brings the subject down to the practical problem of correct treatment based on exact pathologic findings

Diagnosis—The diagnosis is made on the presence of a slightly ulcerating granular weeping itching area of the nipple and areola If in the presence of this area a tumor is found deeper in the breast having signs of malignant growth the diagnosis of Paget's disease is practically certain Frequently no tumor is palpated in the breast in this case it is necessary to take a *biopsy* specimen from the ulcerating area to establish the presence of Paget's cells before a positive diagnosis can be made This latter picture is frequently confused with simple eczema but eczema is usually bilateral and occurs in young persons Paget's disease is always unilateral

Prognosis—The prognosis is good because the mammary carcinoma is very slow to metastasize to the axillary nodes if it is of low grade malignancy while still confined to the breast If metastatic disease once fills the axilla to any appreciable degree the prognosis is poor because it then has acquired all the malignant characteristics of other mammary carcinomas

Treatment—The treatment is radical amputation of the breast and removal of the axillary contents Mistakes are commonly made by not establishing the exact diagnosis and as a consequence the small deeper undiagnosed mammary cancer may not become manifest clinically for several years This is a loss of valuable time so important for cure

III SARCOMA OF THE BREAST

Definition—Sarcoma of the breast is a rare malignant tumor of the mammary

gland which arises usually from the periductal connective tissue

Pathology—Sarcoma of the breast arises from true mammary tissue and also from tissues incidentally resident in the mammary The latter type should not be considered as true mammary sarcoma as it may be of nerve (neurogenic sarcoma) fat (liposarcoma) or lymphoid origin (lymphosarcoma) However these growths are generally included in the sarcomas of the breast as they belong there anatomically True sarcoma of the breast arises usually from a pre-existing fibroadenoma which under the influence of certain unknown factors has changed from a benign to a malignant process involving chiefly the connective tissue

FIG 46.—Sarcoma of the breast The bulky tumor grew to this size in four months It was preceded for many years by a small fibroadenoma.

elements of the fibroadenoma Usually the patient reports that after the tumor had been present for many years sudden rapid growth took place (Fig 467) This is the indication that the malignant metamorphosis has occurred Growth is astonishingly rapid and the tumor soon becomes the size of an orange later the size of a child's head By this time central necrosis has usually occurred from lack of blood supply and there is a bulky foul gray sloughing deeply excavated tumor Hemorrhage is common in those tumors which arise from fibroadenomas Although the neoplastic elements are chiefly from the connective tissue the glandular structures frequently are found scattered through the bulky tumor In fact this type of sarcoma occasionally

also has a carcinoma present within the breast. The presence of chondromas and osteomas is not unusual in a series of cases of any size. The breast sarcomas could be divided on a pathologic basis as arising from

1 A pre-existing fibroadenoma of the breast. This is the most common type.

2 A pre-existing neurofibroma. These benign tumors undergo mutation and assume all the malignant qualities. Their origin is the nerve sheath but usually they are found in patients with other stigmas of von Recklinghausen's disease such as café au lait spots on the integument, the presence of multiple neurofibromas, fibroma molluscum, plexiform neuroma, etc.

3 A pre-existing intracanalicular fibroadenoma. This tumor occasionally gives rise to a bulky cystosarcoma phylloides or "giant" intracanalicular myxoma. The tumor is characterized by its bulk, its cysts and its benignancy.

4 The presence of lymphoid tissue in the breast, especially in the tail of the breast. This has undergone malignant changes and is now lymphosarcomatous.

Diagnosis.—The diagnosis is based on two main points which are pathognomonic, namely, the presence for many years of a tumor and the sudden and rapid growth of this tumor. It soon grows to a large bulky mass, fungates through the skin and metastasizes to the chest, killing the patient.

Prognosis.—The prognosis of mammary sarcoma is very grave. Much depends on which type of origin and what grade of malignancy the tumor represents.

Treatment.—The treatment consists in radical mastectomy. The tumor does not metastasize by the lymphatic route to the axilla, but it frequently happens that separate tumor nodules are present in the region of the original tumor, especially in the low axilla, therefore, wide excision is imperative. The modern treatment of lymphosarcoma and liposarcoma is by irradiation.

RADIOTHERAPY IN CANCER OF THE BREAST

The use of radiotherapy in cancer of the breast is based on the power of radium and x rays to inhibit the growth and reproduction of living cells. Both cancer and normal cells may thus be damaged, although cancer cells are usually more readily affected. The neoplasia is not removed mechanically but is destroyed *in situ*, the body disposing of the debris. For instance, the functioning part of an irradiated cancer of the breast may be sloughed off while its infiltrating base must be absorbed by phagocytes and carried away through the lymphatics. The physiologic and pathologic conditions of the tissues surrounding the cancer and the general health of the patient therefore influence the result of the treatment. The larger the cancer, the larger the area of tissue which is irradiated, the greater is the taxation of the patient's general health.

Radiosensitivity of Tissues Surrounding Cancer.—As irradiation is not limited to the cancer but includes the surrounding tissues, consideration of their resistance to irradiation is important. Normal and cancer cells bearing mitosis and normal tissues and cancers in which the cells divide frequently are believed to be especially sensitive to irradiation. Normal tissues and cancers composed of undifferentiated cells which reproduce rapidly have been regarded as more radiosensitive than those consisting of cells showing greater differentiation and less reproductive activity. Yet among 33 mammary carcinomas irradiated at the Presbyterian Hospital, New York, and classified microscopically, more well-differentiated than poorly-differentiated carcinomas regressed after similar doses of x-ray therapy. There are therefore other additional factors which influence radiosensitivity. The destructive action of irradiation causing death of the irradiated tissues may be recognized clinically when the natural life cycle of the cells composing these tissues has been terminated. Thus the death of short-lived epithelium may be appreciated early, while that of connective tissue, cartilage or bone takes longer to become apparent. A breast which has been intensely irradiated with consequent shedding and subsequent healing of the irradiated skin may grossly appear normal yet on microscopic examination will show obliterating endarteritis and hyalinization of the connective tissue. Such tissue cannot tolerate additional irradiation and has little resistance to infection if opened on or traumatized; it heals poorly and may break down. Because of this lack of resistance, if intense irradiation is given before mastectomy, the incision should be made outside the heavily irradiated area.

Radiosensitivity of Cancer.—The inherent radiosensitivity of most cancers of the breast is greater than that of the surrounding normal breast tissue. After intense irradiation there usually is a gross reduction in the size of the breast tumor, while the normal breast shows much less damage. In a series of 52 patients with mammary cancer irradiated preoperatively or treated only by x rays at the Presbyterian Hospital, New York, the breast tumor regressed markedly in 67 per cent of those treated without much gross change in the irradiated breasts. This reduction was noted in nearly 60 per cent of the tumors which were 3 cm. or less in diameter and in 60 per cent of

those which were 6 cm or more in diameter. The gross clinical reduction was corroborated microscopically. In 9 cases the appearance of the growth in the biopsy specimen before irradiation was compared with that in the mastectomy specimen 2 to 394 days after the last x ray treatment. In these there was noted a marked reduction in the number of mitoses atypical mitoses gigantic or so the other hand pyknotic nuclei vacuolated cytoplasm fibrosis hyalinization of the stroma and occasionally foam cells and cholesterol crystals. In spite of gross and microscopic signs of marked radiation damage to the tumor recognizable cancer cells could be demonstrated in every one of the specimens showing the true radioresistance of these cancers and the difficulty of curing them by these doses of x ray. The result was undoubtedly related to the dosage and microscopically the evidence of radiation damage with greater dosage was more severe. The maximal dosage tolerated by the normal tissues should be given if x ray is chosen as the sole method of treatment as a correlation between definite microscopic types of breast cancer and radiosensitivity are as yet not available.

Relation of Radiosensitivity to Radiocurability.—Radiosensitivity should not be confused with radiocurability. Radiosensitivity is denoted by the immediate regression of a mass to a given dose of radiation. Radiocurability depends not only on the inherent radiosensitivity of the cancer and of the surrounding normal tissues but also on the accessibility of the cancer its natural clinical course if untreated the general condition of the patient the technic of radiotherapy the correct dosage and other conditions.

Relation of Radiocurability to Accessibility.—The effectiveness of radiotherapy in cancer of the breast like that of radical mastectomy, is practically limited to the area which is adequately treated. Cancer cells which are outside of this area are not influenced or are affected very little. For instance irradiation and subsequent regression of the primary tumor in the breast will not influence distant metastases which have not been irradiated. An exception to this rule that the effect of radiotherapy in cancer of the breast is limited to the areas which have been adequately irradiated is found in the regression of skeletal metastases from mammary carcinoma which have not been irradiated directly but which regress after the production of an artificial menopause by irradiation of the ovaries. With this exception radiocurability of cancer of the breast depends on adequate radiation dosage to the primary breast tumor axillary metastases and all other extensions and metastases. It is self evident that it is impossible to appreciate clinically early microscopic loci of cancer and even larger extensions and metastases may also escape recognition and treatment. The larger the primary breast tumor and the regional involvement, the more likely that local extensions and distant metastases may occur and may escape treatment. The five year survival of 73 patients treated by radical mastectomy and postoperative roentgen therapy at the Presbyterian Hospital in New York was found to vary directly with the extent of involvement of the breast and axillary glands. Among 33 patients with inoperable cancer of the breast treated only by x rays at the Presbyterian Hospital during

1939 and 1939 there are 8 who have been free from clinical evidence of cancer for five or more years. None of these patients ever presented any signs suggesting distant metastases and no patient with distant metastases was completely free from signs of cancer for five years although several survived the five year period.

Relation of Radiocurability to the Natural Clinical Course of Cancer.—The natural clinical course of the cancer has a decided influence on the result of radiotherapy. Patients with cancer which progresses slowly continue to show this tendency irrespective of the treatment, while others with more acute and malignant cancer often die in spite of radical therapy. A patient, who twenty four years previously had refused radical mastectomy avoided all medical and until painful skeletal metastases forced her to seek relief by x ray therapy. By this time the cancer had completely destroyed the affected breast and had invaded the adjacent chest wall. Her long survival might have been mistakenly credited to radical mastectomy or radiotherapy had she been treated by these means. In one patient radical mastectomy and postoperative x ray therapy were not instituted until twelve years after the breast tumor had been noted. In another the same therapeutic procedures were carried out one month after she had noted the tumor. The first patient was well at the end of seven years and the second died five months after mastectomy. Neither the successful result in the first nor the failure in the second can be credited wholly to their respective treatment. The natural clinical course of the cancer helped in the first and interfered with successful treatment in the second case. It should be remembered that in 100 untreated cases of cancer of the breast, an average survival period of forty months from initial symptoms to death has been reported by Daland.

Relation of Radiocurability to Infection.—Therapeutic doses of x rays and radium rays have practically no effect on bacteria. Superficial infections in cancer of the breast may be earned off by the radiation slough in deep and undrained infections, vigorous radiotherapy may increase the breaking down and may facilitate deeper bacterial invasion of the tissues. This has no relation to sterile tumor necrosis. Usually such broken-down masses are gradually absorbed under x ray therapy.

Relation of Radiocurability to the General Condition of the Patient.—Aged debilitated persons and patients with diabetes arteriosclerosis and heart disease frequently do not tolerate the intense reaction resulting from the administration of large doses as employed when permanent arrest of cancer by radiotherapy is attempted. This limiting circumstance does not pertain to palliation in which small doses are given as needed and as tolerated by the patient.

Technic of Radiotherapy.—*Methods of Approach.*—The site of the primary tumor in the breast as well as its metastases in the axillae and in the supraclavicular and intercostal regions may be attacked by x ray or radium either applied externally through the skin or internally. In the latter method needles containing radium element or radon (inlum emanation gas) or tiny gold capillaries filled with radon (radio-

seeds) are inserted interstitially into and around the masses of cancer. The needles are removed after the desired number of hours of irradiation. The seeds are permanently buried in the tissues. The radon is used up in one month and the seed if not extruded through the skin becomes inert and is encapsulated like any foreign body.

The external approach has the advantage that large areas suspected of harboring microscopic foci of cancer may be included in the field of intensive irradiation. In this method the deepest parts of the neoplasm are farthest from the source of the rays; the intervening tissues absorb a great deal of the radiation applied on the surface, and the amount of x rays finally reaching the cancer cells may be inadequate for permanent clinical arrest of the cancer. It seems particularly difficult to administer by external x-ray therapy with voltages up to 200 kv., cancericidal doses to deep-seated lymph nodes. A tumor in a pendulous breast may be cross-fired through four or more portals and the radiation dose reaching the tumor thus raised to a maximum tolerated by the surrounding breast tissue. In mediastinal or internal mammary lymph node metastases such cross firing is impracticable and such doses are also not given for fear of injuring the adjacent radiosensitive lung and pleura.

The intensity of interstitial irradiation is greatest in the immediate vicinity of each needle or seed and quickly diminishes with increasing distance from the source. Success depends on accurate placement of these radiating foci; otherwise some parts may be over-irradiated while in others the cancer cells may escape unharmed. The use of this method is therefore limited to accessible, relatively small growths that have not invaded the neighborhood of vital structures. For instance, when cancer has invaded the apex of the axilla the danger of injury to axillary vessels and nerves practically precludes the successful application of this method.

Criterion of Correct Dosage.—Irradiation in cancer of the breast may be given with intent to cure or only to palliate. If an attempt is to be made to cure the patient the maximal amount of radiation which may be tolerated by the adjacent normal tissues is given in all cancers as the cancericidal dose for particular types of breast cancer has as yet not been established. The treatment may consist of a single or of a series of radiation exposures. The treatment should be completed before the appearance of retrogressive radiation changes in the normal tissues. Once finished it should ordinarily not be repeated as a cure by "second" treatment occurs rarely and there is great likelihood of permanent radiation damage to the normal tissues. Palliative radiotherapy on the other hand is administered in small doses which may produce growth restraint but do not permanently arrest the growth of cancer. This radiation is repeated as needed and tolerated by the patient. The dosage is dictated not by the desire to cure but by consideration of the tolerance and comfort of the patient. Large doses which may produce severe local or general reactions are avoided.

It is difficult to estimate the correct dosage which in a given case will cure breast cancer. In 33 cases of cancer of the breast treated preoperatively with x-rays at the Presbyterian Hospital, New York, cancer cells

were found microscopically in the mastectomy specimens 2 to 331 days after the last x-ray treatment though grossly these specimens did not show any evidence of persisting cancer. The dosage used in these cases was only a little less than that applied in the 8 out of 35 inoperable cases treated in 1934 and 1939 in which the patients have been free from clinical evidence of cancer for five years or longer after x-ray therapy. There is no assurance that in some of these eight patients temporarily quiescent cancer cells may not again start growing in the future. A five-year freedom from clinical evidence of cancer has been accepted as the criterion of cure for radical mastectomy. After radiotherapy the site of the primary tumor and regional nodes remain in situ in contradistinction to the removal of these possible sources of future growth by the radical operation. In spite of this important difference however and in order to have at least a somewhat comparable standard for evaluation of these two methods of treatment it seems fair to adopt a five-year clinical freedom from cancer as a criterion of clinical cure by radiotherapy. The average dosage estimated to reach the site of the cancer in the 8 clinically cured cases was calculated to vary between 5000 and 6000 r or about nine to ten times the dose which if applied to the skin in one exposure would produce a mild erythema. Perhaps this is the correct dosage for cancer of the breast.

Indications for Radiotherapy.—Radiotherapy of cancer of the breast may be employed as the only treatment or combined with operative removal of the primary tumor and axillary metastases.

Radiotherapy in Inoperable Cancer of the Breast.—The value of radiotherapy in inoperable cancer of the breast is generally accepted. Practically no other form of treatment is available in these cases except in the rare instances in which destruction by heat or caustic might be preferable. With the proper use of radiotherapy ulcerated surfaces may be healed, large tumors may be reduced in size, attachments to the sternum and ribs may be absorbed, pain due to pressure on nerves or to bone invasion may be relieved, the general condition of the patient may be improved and at times the disease may be arrested. This may be done with interstitial or external application of radium or roentgen therapy.

Radium needles inserted into the primary cancer in the breast and the regional lymph node areas gave good results in the hands of Geoffrey Keynes of London. These results were not obtained by others using his method and in recent years interstitial radium has not been used much in cancer of the breast in the United States.

X-ray therapy has been administered for inoperable mammary cancer for over forty-five years. Regression of the primary tumor in the breast after x-ray therapy does not determine the progress of the disease as a whole if distant metastases are present. It is more the latter factor which influences the clinical course of the case, and if distant metastases are present the x-ray dosage to the breast tumor is moderate as it is given for symptomatic relief such as to heal ulcerations, relieve pain, etc., and cure is not attempted. If on the other hand the disease clinically has not spread beyond the breast and axilla and an attempt is to be made

to control it permanently by radiotherapy maximal x ray doses to the breast and axilla are indicated. This type of treatment should not be applied until careful clinical and radiographic search for local extensions and distant metastases suggests that the disease is limited to the breast axilla and perhaps one supra-clavicular area and that the patient will tolerate the treatment. Once this has been decided accurately installed daily x ray exposures are applied cross firing the tumor in the breast axilla and if need be in the supraclavicular area. This should be done by someone familiar with the disease and the physical distribution of the irradiation applied to these anatomical parts. Each treatment should be done as carefully as when a surgeon undertakes to do radical mastectomy. Only if treatment is carried out in this manner may one hope for better results.

Radiotherapy in Operable Cancer of the Breast.—In view of the decided influence which the extent of the cancer at the time of treatment has on the results which may be expected from radiotherapy in operable cancer of the breast it is not surprising that the results of this treatment in cancer limited to the breast have been better than those just quoted in inoperable cases. However radiotherapy in these cases is still experimental. Months after irradiation of a cancer of the breast with resulting marked diminution in size microscopic examination of a specimen removed for biopsy may reveal the presence of well stained cancer cells and mitoses. While long-continued clinical freedom from symptoms may result from irradiation late reactivation of the primary growth and metastasis cannot be excluded. Radical mastectomy is therefore still the accepted method of treatment in early operable cases in which the disease is clinically limited to the breast. A patient whose poor general condition contraindicates surgical intervention should be given radiotherapy. Clinically very malignant rapidly growing inflammatory cancer common in young women especially during pregnancy is also best treated by irradiation. Radiotherapy is preferable for this group in spite of poor results as radical mastectomy is frequently followed by wide dissemination of the disease.

Radiotherapy of Metastases.—Skin metastases can usually be made to disappear by radiotherapy. Occasionally they reappear although in exceptional cases even cancers "en cuirasse" may be held in check for several years. Metastases in operative scars may be difficult to control as occasionally necrosis of the scar results following vigorous irradiation with cancericidal doses.

Röntgen therapy of skeletal metastases is usually followed by diminution of pain and frequently by recalcification of areas of bone absorption. If a clinical diagnosis of skeletal metastases has been made x-ray therapy should be given even if x-ray films fail to show the metastases. In 11 such patients followed by monthly x-ray films at the Montefiore Hospital New York a diagnosis of skeletal metastases was made and x-ray therapy to the affected areas started from one-half to twelve months before the x-ray films finally showed the suspected skeletal metastases. In addition to the radiotherapy Brunschwig advises the daily administration of 10 to 15 Gm of calcium gluconate over a 4 week period of time. Support for a weakened spine

and relief of pain caused by pressure on a partially destroyed vertebra may be obtained by the use of spinal braces or a stiff corset which reaches at least up to the angle of the scapula. This help is especially useful before healing secondary to the x-ray therapy. In spite of improvement of these patients after radiotherapy, the majority die less than a year after the onset of symptoms. In exceptional cases however extensive metastases have been controlled for from a few to twenty years and bedridden patients have obtained economic restitution. Improvement in non-irradiated skeletal metastases has been noted after castration incidental to roentgen therapy of metastases in the pubis and iliac bones. Roentgen castration is usually carried out in skeletal metastases from cancer of the breast in addition to radiotherapy directed over the metastases in the bone.

Röntgen therapy is only of temporary palliative value for the majority of pulmonary metastases as they usually occur in the terminal stage of the disease. In some cases however metastases in the lungs and pleurae have been held in check for five and six years though eventually death was caused by the disease.

Metastases in the abdominal viscera respond only slightly or not at all to roentgen therapy and usually progress rapidly until the end.

Metastases in the brain spinal cord and retina have been temporarily controlled by roentgen therapy. While for a time there is regression of symptoms they usually recur within a few weeks or months and then further treatment is futile.

Preoperative Roentgen Therapy.—As a comparison of the microscopic structure of the preirradiation biopsy material and the 9 postirradiation mastectomy specimens mentioned earlier showed a marked reduction in the number of mitoses monster and shadow cells and other evidences of radiation damage it does not seem too far fetched to think that vigorous preoperative radiotherapy in tumor doses of 1000 r or over may tend to reduce the viability of the tumor and the likelihood of local persistence and distant spread of the cancer. There is only little support for the belief however that 1000 r or less will do more than temporarily reduce the number of mitoses. Preoperative radiotherapy should be limited to those few cases in which a definite decision cannot be made as to whether the case is operable or not. A rigid application of the rules of operability will probably lead to classifying them as inoperable and transfer them to radiation therapy instead of trying to combine both methods. If full radiation dosage is given preoperatively a period of delay lasting for six to eight weeks that is until every vestige of erythema has disappeared is essential before mastectomy may be performed. In regard of this precaution has resulted in non-healing wounds.

Postoperative Roentgen Therapy.—As shown by microscopic study of preoperatively irradiated patients and the five year follow-up statistics of non-operated patients the cancericidal x-ray dosage for most carcinomas of the breast is much higher than that which is usually applied to the thin poorly nourished post-mastectomy skin flap covering the chest and axilla and over the supraclavicular intercostal internal mammary and paravertebral chains of lymph nodes. Therefore one cannot hope ordinarily to destroy the postoperative

x ray therapy the cancer remaining in these areas after the operation. Nevertheless statistics which show a larger proportion of five year survivors when radical mastectomy is followed by x ray therapy suggest that a certain amount of temporary growth restraint may be obtained by lesser x ray dosage. We do not advise the routine use of postoperative x ray therapy but apply it in occasional cases in which the operator believes that he did not remove the entire cancer. The radiation is then applied to the supraclavicular and internal mammary lymph node chains in the hope of causing temporary growth restraint in these areas. The mastectomy and axillary regions are irradiated only if the operator believes that cancer may persist in these areas.

Irradiation of the Ovaries.—Roentgen castration of all women with cancer of the breast before the menopause has been advised. The only definite proof of benefit from this procedure is found in the regression of non irradiated skeletal metastases in other cases it should not be carried out routinely.

Summary.—Successful radiotherapy of cancer of the breast is based on familiarity with the disease, appreciation of the factors governing the relative radio sensitivity of cancer and the tissues surrounding it, as well as the correct irradiation of all parts of the growth.

Radiotherapy is the treatment of choice in inoperable and metastatic cancer of the breast. Similar treatment in operable cancer clinically limited to the breast is as yet experimental and is justified only in certain exceptional cases. Radical mastectomy being preferable provided rigid classification of operable and inoperable cases is carried out. Preoperative and postoperative roentgen therapy may be of value in some cases for temporary growth restraint of the cancer.

TRAUMATIC FAT NECROSIS, TUBERCULOSIS AND SYPHILIS OF THE BREAST

TRAUMATIC FAT NECROSIS

Definition.—Traumatic fat necrosis of the female breast is a benign disease which occurs as the result of severe trauma to a very fat breast. As the clinical signs and symptoms closely parallel those of carcinoma, the disease is commonly mistaken for cancer of the breast.

Etiology.—The lesion occurs only in breasts which are unusually corpulent. The average weight of the patients in the twenty cases reported by Lee and Adair was 176 pounds. An injury of severe nature takes place causing extravasation of blood into the fat tissue of the breast. The injuries have frequently been caused by the introduction of long hypodermic needles following some severe operation. The large needle punctures one of the numerous veins of the breast permitting extravasation of blood into the interductal areolar tissue and into the thick fat pad overlying the mammary tissue. The lesion results also from such severe injuries as a fall down a flight of stairs. In one instance the patient fell down stairs holding a picture frame under her arm. The corner of the frame ran into the breast without breaking the integument but resulted in the production of a marked ecchymotic area.

Pathology.—Necrosis of the fat tissue occurs both as a direct result of injury and also as a result of hemorrhage in the local tissues. Necrosis occurs very soon after the injury. Many giant cells appear and have been seen in tumors in as short a time as five weeks. There is lymphocytic infiltration associated with a marked production of fibrous tissue. One feature is that of an obliterating endarteritis. Frequently, numerous small cysts of fluid fat are scattered through the lesion. Later on the mass contracts; there is a considerable growth of new spin-

dle fibroblasts, and more and more fibrous tissue forms. The lesion may contain calcium deposits, and at times the wall of a cyst may be calcific or the cyst contents may be fluid oil and admixed with small stones of calcific material.

Symptoms and Diagnosis.—After the hemorrhage which follows the injury has been absorbed, a painless, stony-hard tumor forms. It may become attached to the overlying skin, retract the nipple, deform the shape of the breast (Fig 468) and even be attached to the deeper structures, such as the pectoralis major muscle. The diagnosis is based on (1) the history of a severe injury which occurs in (2) a very fat breast.

Fig 468.—Traumatic fat necrosis of the female breast showing the characteristic puckering and skin attachment. A tumor is present possessing all the clinical signs of cancer. This benign tumor resulted from the introduction of hypodermic needles beneath the breast.

(3) A painless, stony-hard tumor is present which (4) causes attachment to the skin, retraction of the nipple and deformity of the breast.

Prognosis and Treatment.—As traumatic fat necrosis of the breast is a benign lesion, local removal of the tumor will effect a cure.

TUBERCULOSIS OF THE BREAST

(*Tuberculous Mastitis*)

Definition.—Tuberculosis of the breast is a rare lesion (which is becoming rarer) caused by an infection of the mammary tissue with the tubercle bacillus. It was first described by Sir Astley Cooper in 1829.

Etiology and Pathology.—The tuberculosis in this instance is thought by some to be primary in the breast, the result of a blood-borne infection. Another school of thought stoutly maintains that all mammary tuberculosis is secondary to tuberculosis in other parts, such as rib, lung, pleura, mediastinum sternum, cervical or axillary node

involvement. The latter view is more common and is explained on the ground of retrograde lymphatic extension. The axillary lymph nodes are involved in about 60 per cent of the cases. The tuberculous mastitis is usually a localized process. The lesion develops to the stage of tissue liquefaction and the formation of a true tuberculous abscess. The abscess burrows up through the breast, appearing by one or more sinus tracts at the surface of the skin, where it breaks discharging the characteristic tuberculous abscess pus.

Symptomatology and Diagnosis.—A soft tumor mass is present in the breast. The lesion is painless except immediately before

the rupture of the abscess when it again becomes painful. The differential diagnosis must be made chiefly from a fungating carcinoma from actinomycosis and from pyogenic mastitis. About the sinus tracts a deeper pigmentation takes place on the skin surface. The nipple is commonly retracted especially if one of the fistulas appears within the areola. The clinical diagnosis is frequently difficult but is based on the multiplicity of sinus tracts on the discharge of the characteristic tuberculous pus on the presence of a soft breast tumor on the microscopic proof of the presence of tubercle bacilli in the smear and on the x-ray film demonstration of pulmonary rib or mediastinal tuberculosis.

Prognosis and Treatment.—The prognosis is usually good depending however on the extent of the disease process in the other parts of the body. Frequently local surgical removal of a section of the breast is not curative because the sinus tracts are tortuous and the operator is quite apt to leave behind an area of tuberculous mastitis in which another abscess will develop later. Local mastectomy usually effects a cure unless the axillary nodes are involved in which case an axillary dissection is indicated. It is not necessary, however to remove the pectoral muscles. It is highly important that the operation be followed by general hygienic treatment.

SYPHILIS OF THE BREAST

Definition and Etiology.—Syphilis of the breast consists of one or multiple lesions of the breast or nipple caused by infection with the *Treponema pallidum*. It is a rare local manifestation of a general disease. In a series of approximately 4000 patients with lesions of the breast admitted to the Memorial Hospital in New York City there were 2663 cases of cancer, 180 of fibroadenoma, 16 of sarcoma, 20 of Paget's disease, 1600 of subacute and chronic mastitis and only 2 (0.05 per cent) of syphilis of the breast.

Pathology.—The form taken by the le-

sion is dependent on the stage of the syphilitic infection. 1 *The primary chancre* of the breast is usually localized on the nipple, is usually bilateral and is the most common syphilitic lesion. In days past when wet nursing was frequently employed it was not uncommon for a wet nurse with syphilis to infect the mouth of an infant who in turn might transmit the infection to his parents. The reverse of the process was also true. 2 *The secondary stage.* The skin of the breast is frequently the site of syphilitic eruptions. Mucous patches may occur about the nipple. 3 *The tertiary stage.* The gumma is an extremely rare manifestation of a syphilitic lesion. Among approximately 7000 cases of breast lesions at the Memorial Hospital there was but one gumma. The gumma is an intraparenchymatous lesion. At times it appears in a subareolar position causing ulceration and sometimes total destruction of the nipple.

Diagnosis.—The chancre of the nipple and the subareolar ulcerating form of gumma are difficult to differentiate from Paget's disease. The characteristic appearance of chancre however will aid in distinguishing it. The diagnosis can be easily verified histologically by biopsy and also by the Wassermann and Kahn tests. A therapeutic test with doses of arsenphenamine will also help in the diagnosis. The gumma commences as a firm localized mass gradually pressing against the skin from beneath causing a dusky and later a localized red area which becomes purple. The tumor at this stage softens, becomes fluctuant and if cut into will exude typical necrotic material. The wound is grizzly, his overhanging edges are unhealthy in appearance and will not heal. The diagnosis of syphilis of the breast is based on the anamnesis including the history of exposure, primary and secondary manifestations, misadventures, serological reactions, biopsy, dark field examinations, etc.

Prognosis and Treatment.—The prognosis is favorable for a complete cure of the lesion if the proper antisyphilitic therapy is carried out. This should include penicillin.

DISEASES OF THE MALE BREAST

In considering the diseases of the male breast it must be borne in mind that the breast in the male is a rudimentary organ yet occasionally most all the diseases common to the female breast may be observed.

Anomalies—The congenital anomalies of the breast are amastia (absence of the breast) polymastia (supernumerary breasts) athelia (absence of the nipple) and polythelia (supernumerary nipples). These are rarely observed in the male.

Gynecomastia which may be defined as excessive size of the mammary gland or glands in the male may occur in youth young adult life or middle life and is either idiopathic or associated with disturbances of the sexual glands inflammations such as mumps or the result of direct trauma on the breast. The treatment should always be conservative operative intervention (resection of the breast leaving the skin and nipple or mastectomy) being resorted to only if the breasts cause mental or physical suffering. More recently x-ray therapy has been suggested but this seems to be of doubtful value. Testosterone propionate the male sex hormone is of some value and should be tried before resorting to surgical treatment.

Infections and Inflammations—Infections and inflammations may occur in the male breast but occur much less frequently than in the female. All the pyogenic infections common to the skin may occur on the breast and nipple such as furuncles boils cellulitis and even abscesses. Inflammatory lesions due to pyogenic infections may cause eczematous conditions of the nipple and areola sometimes giving rise to infection of the ducts or acute mastitis.

Acute mastitis is rare in the male except soon after birth that is it may occur from the fourth to the twentieth day of the newborn infant's life or at the time of puberty. It manifests itself by painful swelling redness and tenderness and at times even by a discharge of a milk like substance. It usually requires no treatment especially no massage but the patient may be made comfort-

able by the use of hot or cold antiseptic applications. Injury to the male breast some times leads to acute mastitis with or without abscess formation.

The treatment of infections of the male breast should follow strict surgical principles. The use of soothing applications antiseptics or antiseptic ointments and if abscess formation occurs incision and drainage constitute the course to follow.

Chronic interstitial mastitis or chronic hypertrophic mastitis is a rare distinct clinical entity and may occur at any time from adolescence to old age. The causative factor is unknown but it has followed in the wake of acute mastitis and injuries. This disease may be diffuse or localized. Diffuse involvement is noted particularly below the nipple or areola and when localized is in the form of hard nodules which are not encapsulated. Pain may or may not exist and may be variable in its severity.

The proper treatment consists of soothing applications or ointments containing ichthylol mercury or iodine and the administration of iodids internally. If palliative treatment does not suffice after a reasonable time mastectomy may be necessary for the relief of pain.

The granulomatous infections such as tuberculous syphilis and actinomycosis have occasionally been observed in the male. These lesions are usually of a low grade inflammatory nature with the formation of indurated nodules or diffuse infiltrations which in the period of weeks or months may cause some pain and swelling redness of the skin and finally ulceration with sinus formation.

The importance of these granulomatous processes is that occasionally, before the breaking down and the formation of sinuses these tumorous masses may simulate malignant disease in that the skin may be adherent and retracted the tumor mass may be poorly defined and the lymph nodes in the axilla may be enlarged. The proper histologic and pathologic examination of tissue and pus will make the diagnosis certain.

The treatment of tuberculous mastitis is the general hygienic regime of all tuberculous patients including heliotherapy and conservative surgical procedures for the eradication of the local disease.

Syphilis of the Breast—Syphilis of the breast may present itself in the form of cutaneous lesions or gummas. Characteristics of syphilitic manifestations such as gummas can be corroborated by complement fixation tests or therapeutic tests of mercuric bismuth iodide and other specific remedies which usually cause a prompt regression of the disease.

Actinomycosis—Actinomycosis may be differentiated from other lesions by the finding of sulfur like granules in the pus from abscess cavities or sinus tracts which will show the presence of actinomycetes. Conservative surgical treatment such as excision of the abscess cavity or eradication of the sinus tracts or ulcerating areas together

the breast areola or nipple are those common to the skin in general that is the basal cell epithelioma squamous cell epithelioma and malignant melanoma.

Tumors in the breast proper include the fibroma lipoma angioma or lymphangioma fibroadenoma cystic adenoma serous cyst retention cyst galactocele and papillary cyst. Malignant tumors of epithelial origin are duct carcinoma (at times presenting the appearance of Paget's disease) adenocarcinoma and papillary carcinoma. All may at times be spoken of as a scirrhous or medullary type depending on the amount of connective tissue proliferation in the tumor.

Of the connective tissue tumors there are various types of sarcoma. The fibrosarcoma

Fig 469.—Carcinoma of the left breast, with metastases to the axilla in a man aged fifty three. It was treated surgically and by radium in 1899. He died from metastases to the lung and mediastinum five years and one month after admission to the hospital.

with the use of copper sulfate iodide and irradiation is recommended. Since the introduction of the sulfanilamide preparations a few isolated case reports of treatment of actinomycosis with this drug have been recorded with marked beneficial results. More recently penicillin has proved to be a valuable agent in the treatment of this disease.

Malignant and Benign Tumors—Malignant and benign tumors of the breast proper may be divided into those originating in the epithelial cells and those originating in the connective tissue cells. The benign tumors which may occur in the skin areola or nipple are the fibroma fibropapilloma angioma nevus and sebaceous cyst. The malignant tumors which may involve the skin of

(spindle cell) is the most common and then the adenosarcoma depending on the presence of epithelial elements in the tumor. Occasionally rare types of sarcoma such as lymphosarcoma neurogenic sarcoma osteochondrosarcoma endothelioma and liposarcoma have been described.

Tumors benign and malignant may occur in the male breast at any time from the twentieth year to old age.

Diagnosis—The differential diagnosis between benign and malignant tumor of the male breast is at times very difficult. Generally the characteristics of benign tumors may be described as follows: tumorous masses which vary in size from a few millimeters to several centimeters in diameter

As a rule they are sharply defined firm in consistency movable on the underlying tissue and beneath the skin and slow in growth. In the case of cysts a sense of fluctuation may be obtained and no shadow is cast on transillumination if they contain clear fluid. If the fluid is turbid or bloody opacity to transilluminated light is observed. Other tumors give shadows depending on the density of the tissue from which they are derived. However the transillumination of the male breast while valuable is very difficult because of the small size of the organ.

At times most all of these characteristics may be encountered in a malignant neoplasm of the male breast but more often they are tumors varying in size which are not tender are hard in consistency and poorly defined tending to merge with the surrounding breast tissue. When seen later they are adherent to the skin as is evidenced by the pig skin or orange peel appearance and still later they may be adherent to the underlying tissue with enlargement of the axillary nodes which are hard in consistency. Ulceration pain and bleeding as a rule are late symptoms.

The benign tumors when favorably situated sharply defined and not too large may be removed by local resection or enucleation. However the correct diagnosis of diseases of the male breast may be so obscured that mastectomy is preferable.

Treatment—The treatment of malignant diseases of the male breast should always be radical especially when they are seen early that is when the tumor involves the breast with no demonstrable metastases in the axilla. By radical mastectomy is meant sacrifice of both pectoral muscles with dissection of the axilla wide excision of the fascia and of the skin overlying the breast (Halsted or

Willy Meyer operations). In other words operative treatment should be as radical in the male as in the female. The prognosis in malignant diseases of the male breast is always guarded for as a rule these patients do not appear for treatment early. The possibility of a cure is directly proportional to the anatomic involvement by the tumor. Five year cures should be as good as in the female breast. When the disease has spread to the lymph bearing areas the prognosis is much more serious.

In view of the advancements in radiation therapy which have been made in the past decade today all malignant diseases of the male breast should have if possible preoperative and postoperative irradiation with x ray or radium.

Deaver and McFarland in their series estimate that 1.5 per cent of all malignant breast tumors and 2 per cent of all benign tumors occur in men and that 80 per cent of the tumors of the male breast are malignant. A total of 136 per cent of all the malignant breast tumors in patients admitted to the New York State Institute for the Study of Malignant Diseases were in men 44.4 per cent of these being malignant. In women 73 per cent of all the lesions were malignant.

XXII. THE THORACIC WALL, PLEURA AND LUNGS

PHYSIOLOGY, ANOMALIES AND TRAUMATIC EMPHYSEMA

THE MECHANICS OF RESPIRATION

Access in surgery of the thorax is dependent on a high understanding of the mechanics of respiration and of the pathologic physiology of open and closed pneumothorax. While a knowledge of other aspects of respiratory physiology is important and in all will increase the surgeon's efficiency, it is absolutely essential for him to comprehend the mechanism of breathing and to know how to handle and prevent untoward train of events which follow opening of the pleural cavity or mobilization of the thoracic

the fetus as a result of its position and the absence of muscular tone the thorax is so contracted the cavity is no larger than the relaxed lung and air enters. At birth the straightening of the body and contraction of the muscles of respiration increase size of the thorax. This increase is permitted and is gained by stretching of the lungs and aspiration into the bronchial and alveolar spaces. After the birth the lungs are always stretched and always fully filled with air. This is the mechanism of the maintenance of the negative intrapleural pressure. It is spoken of more accurately as the tension of the pleural cavity (a pressure of 8 cm. of water) under which the lungs are stretched to fill the thorax and as being dependent on a disproportion between the capacity of the chest and the size of its contents. As the thorax expands on inspiration by contraction of the respiratory muscles the lungs are still further stretched more air is drawn into them. On expiration as the thorax contracts they are permitted to draw in toward the chest and expel the air inhaled in the preceding action. In other words the lungs passively follow movements of the expanding and contracting thorax and as they do so air is inhaled and exhaled. When an opening is made in the thoracic wall the thorax contracts and air is sucked into the pleural cavity. The lung on the affected side draws away from the thoracic wall and the one on the opposite side is pulled toward the midline. On inspiration as the thorax increases in size, more air is drawn into the pleural cavity, and the mediastinum follows the thoracic wall and shifts further over. On expiration as the thorax decreases in size, air is forced out of the pleural cavity and the mediastinum is pulled back toward the midline. A wound through the thorax thus enters and leaves the thorax on respiration is called a sucking wound and the to and fro movement of the mediastinum is called mediastinal flutter. It is obvious that this movement of air in and out of the wound is similar to breathing but that it is a useless interchange because the air merely enters and out of the pleural cavity and does not come in contact with any oxygen absorbing surface.

The subject is thus breathing both through the normal air passages and through the hole in the thoracic wall. The larger the hole, the more air goes in and out of it and the less goes in and out of the nose and mouth. If the opening is small (smaller than that of the glottis), normal respiration will usually be sufficient to support life but if it is large asphyxia and death will ensue. This is the mechanism of open pneumothorax.

There are certain pathologic conditions which prevent the untoward effects of open pneumothorax and certain ways in which they can be prevented artificially. Adhesions between the lung and the thoracic wall prevent collapse of the lung and movement of the mediastinum and since one lung functioning normally is ample to carry on respiration any infection that fixes the mediastinum and makes it rigid prevents "flutter" and permits efficient breathing. At operation if such symptoms develop they can be stopped by grasping the lung and drawing it into the opening in the thoracic wall. This partially closes the opening and also stabilizes the mediastinum. A sucking wound of the chest should be closed immediately by packing until the patient can be transported to the operating room.

PRESSURE ANESTHESIA

During a surgical operation involving wide opening of the pleural cavity collapse of the lungs may be prevented by raising the pressure within them. This can be accomplished most simply with the ordinary apparatus and mask used for gas anesthesia. Many of the devices now on the market are so constructed that the pressure under which the gas is administered can be controlled and varied. If a device with these improvements is not available the older type may be adapted by connecting the exhalation outlet by means of rubber piping with a glass tube which can be lowered into a bottle of water to any desired depth. A resistance of from 3 to 5 cm. of water is ample. During the operation the distention of the lung can be controlled by raising or lowering the glass tube. A pressure much above 8 cm. of water should be avoided as there is some danger of rupturing the lung.

ANOMALIES OF THE THORAX

Anomalies of the thorax and its contents are numerous. The more serious anomalies are not compatible with life, and few of those that permit life interfere with function to such an extent as to warrant attempts at correction. Congenital elevation of the scapulae is not uncommon. One or both pectoral muscles on one or both sides may be absent. The sternum may be separated into two parts by a vertical cleft or may be deeply depressed toward the spine. Torking of a rib anteriorly is common as is also fusion of

two ribs There may be an extra rib in either the cervical or the lumbar region or the first or twelfth rib may be absent or rudimentary The whole or a part of other ribs may be missing

Anomalies of the lungs range from complete absence or hypoplasia of a lobe one lung or both lungs to the presence of supernumerary lobes These variations are of considerable importance in the localization of parenchymal bronchial or interlobar disease

The congenital anomalies which are of surgical importance are cervical rib pectus excavatum and congenital hernia of the lung Cervical rib congenital thoracic tumors and bronchial anomalies will be discussed in another section

Pectus Excavatum (Trichterbrust Funnel Breast)—*Definition*—A deformity of the thorax usually congenital but occasionally traumatic in which the sternum is depressed toward the spine sometimes to such an extent that symptoms are produced from compression of the heart

History—The first known description of the condition was given by Johann Schenck in the sixteenth century Wilhelm Ebstein in 1882 reported five cases described the symptoms and first used the term trichterbrust Ludwig Neyer in 1911 was the first to attempt to correct the deformity surgically James Carr reviewed the literature in 1933

Deformity—The condition occurs commonly in persons of an asthenic habitus The depression starts at the manubriosternal articulation and increases steadily to the xiphoid which is frequently depressed to within a few centimeters of the spine The transverse diameter of the chest and the anteroposterior diameters in the midclavicular lines are increased The cartilages sink abruptly backward to the depressed sternum

The heart is usually displaced to the left and rotated on its axis but occasionally it remains held in a normal position A depression on the anterior surface of the right auricle from the sternum has been noted

Symptoms—Usually there are no symptoms referable to the condition This is especially true if the heart has escaped well to the left When symptoms are present they vary from mild intolerance of severe exercise to marked dyspnea palpitation tachy-

cardia and precordial pain In the case reported by Carr and in which the writer operated there were recurrent attacks of unconsciousness

Treatment is surgical and consists in resection of the portions of the sternum and cartilages which are pressing on the heart This usually includes the lower half of the corpus sterni and the cartilages attached to it Operation should be resorted to only if the symptoms are handicapping and if they can definitely be attributed to the deformity

TRAUMATIC EMPHYSEMA

Injury of any part of the respiratory or gastrointestinal tract may permit the escape of air into the tissues In the respiratory tract especially in the lung such a wound has a tendency to become valvular permitting the escape of air during one phase of respiration or on strong respiratory efforts and closing during the other phase to prevent its return In this manner, air is pumped forcibly to all parts of the body until the patient becomes seriously inflated

The condition occurs most commonly after a penetrating crushing or contusing injury of the thorax The fracture of ribs is not necessary The lung may be torn by the severe expiratory efforts of coughing or the straining incident to childbirth High pressure gas anesthesia or explosion of an anesthetic administered by the closed method may produce it The trachea or bronchi may be injured by foreign bodies or during bronchoscopy

An interesting group of cases follow tonsillectomy extraction of teeth and other operative or accidental wounds of the mucous membranes of the mouth nose and throat.

Generalized traumatic emphysema secondary to injury of the lung may disseminate by one of two routes If the lung is torn on its surface tension pneumothorax may force air through a wound of the parietal pleura into the tissues of the thoracic wall and thence over the whole body If the injury to the lung is internal the air is forced along the peribronchial and perivascular tissues to the mediastinum whence it travels upward to appear first in the supraclavicular fossae and downward retroperitoneally to appear in the groin

JEROME R HEAD

INFLAMMATIONS OF THE CHEST WALL, ETC

INFLAMMATIONS OF THE CHEST WALL

A Subpectoral Abscess—A subpectoral abscess is an uncommon although serious lesion and because of its location beneath heavy bellied muscles it is frequently misdiagnosed in its early development. The infection begins in the subclavicular glands at the extreme apex of the axilla and is usually caused by a hemolytic streptococcus secondary to an infection or injury of the hand, arm, axilla or breast. It also may follow an injury of the chest wall or of the supraclavicular fossa.

The subclavicular glands lie adjacent to the axillary vein high in the axilla and just beneath the costocoracoid membrane. When the infection extends outside of these glands it spreads downward and outward beneath this fascia and at times may extend posteriorly around the chest wall to the subscapular region.

Symptoms—Since the infection lies deeply hidden from the surface local symptoms and findings are insignificant in the early stage and are usually preceded by fever, chills and general malaise. Pain in the shoulder and arm especially on adduction or rotation, rigidity of the pectoralis major muscle and a sensation of tenderness or pain near the middle of the clavicle are the first local manifestations. Examination reveals an early local abnormality but later swelling and a fullness near the outer inferior border of the pectoral muscle with tenderness over this area are noted. Much of the swelling may be due to edema and the lack of fluctuation is misleading, often delaying the diagnosis.

Treatment—Treatment consists of incision and adequate drainage along the outer inferior margin of the pectoralis major muscle. Additional drainage by division of the muscle fibers beneath the clavicle may be necessary. Owing to the location of the abscess pyemia and septicemia are not uncommon. The condition is always serious and the prognosis must be guarded.

B Subscapular Abscess—A subscapular abscess is much less common than a subpectoral abscess and usually produces few local or systemic symptoms. Although caused

by pyogenic organisms it may present the appearance of a cold abscess. At times it is differentiated from tumors only by the presence of fluctuation. Treatment consists of adequate drainage after determination of the etiologic organism by aspiration.

C Acute Osteomyelitis—Acute osteomyelitis of a rib may result from drainage of an empyema from trauma or from general staphylococcal infections. With the exception of the last mentioned the systemic involvement is much less common than that produced by infection in other bones. Involvement of the cut end of the ribs following rib resection for draining an empyema is not uncommon and produces no systemic reaction. Care must be taken that the sequestered end does not cause a chronic empyema by falling into the cavity and acting as a foreign body. Occasionally an entire rib may become involved and sequestrate. Surgical removal of the sequestrum is followed by complete healing. Osteomyelitis following trauma to a rib produces no special problem and is treated in the usual manner for this lesion. Osteomyelitis of the sternum is much less common but when present carries a high mortality.

Typhoid osteomyelitis of a rib is rarely seen since the incidence of typhoid fever has been reduced. The local condition may not appear for months or years after an attack of typhoid fever; however a history of an attack is usually present. Locally a fluctuant swelling develops but signs of an acute inflammation are lacking. Its recognition is important in order to prevent spread of the organisms before the diagnosis is made. Typhoid osteomyelitis must be differentiated from tuberculosis, syphilis, sarcoma and chronic pyogenic infections of the rib. Aspiration and culture along with a history of typhoid fever are usually sufficient for establishing the diagnosis. Treatment consists of surgical excision of the involved bone.

D Tuberculosis—Tuberculosis of the sternum, ribs and cartilages is a common lesion. It may develop by one of two methods either by direct extension from tuberculous glands lying just outside the parietal pleura usually near the sternum or by hematogenous spread from an active tuberculous lesion elsewhere in the body. The

former route is probably much more common since in many cases the tuberculous infection is around the rib or cartilage with no evidence of infection found within these structures.

Although this infection may occur at any age it is more common during middle life. The lesion presents local manifestations similar to those produced by cold abscesses elsewhere. There is little evidence of local inflammation, a fluctuant non tender swelling indicating its presence. If it is allowed to progress necrosis of the skin occurs with sinus formation. The infection may however extend quite some distance along a rib or cartilage before sinuses develop. Aspiration of the swelling reveals thick curdy pus. If a sinus is present injection of a radio-opaque material and x ray examination of the chest wall aid in determining the limits of the involvement.

Treatment—Treatment consists of wide surgical excision of the involved rib or of the entire cartilage if the latter is involved. When no sinuses or secondary infection is present closure of the wound without drainage is indicated. Supportive treatment as for tuberculosis elsewhere is helpful.

E. Actinomycosis—Actinomycosis of the chest wall is practically always secondary to actinomycosis of the lung or intestine. In the former case the process extends outward through the pleural cavity and in the latter, extension is up through the diaphragm. Since this infection respects no tissue boundaries it involves all structures of the chest wall and slowly produces a brawny induration in the soft tissues with considerable swelling and edema. A productive cough usually with hemoptysis and local pain and tenderness are experienced along with constitutional symptoms of fever, weakness, sweats, anorexia and loss of weight. If the disease process is allowed to continue discharging sinuses are produced.

This condition may be mistaken for tuberculosis of the chest wall or tumor of the lung with secondary invasion of the chest wall. The diagnosis is established by the finding of sulfur granules in the exudate and the ray fungus on staining material removed by aspiration or biopsy.

Treatment—Treatment consists of wide excision of the involved parts usually per-

formed best in several stages. The use of thymol and potassium iodide by mouth and thymol locally has been of definite benefit in some cases. Local x ray treatment may also be helpful. The prognosis is poor. Response to therapy is usually only temporary, the disease often recurring after a seemingly permanent cure has been effected.

HERNIA OF THE LUNG

This is a very uncommon condition, only 171 cases having been reported in the literature up to 1933. The condition may be congenital or may develop following trauma to the chest wall. The congenital type is a true hernia with a sac of parietal pleura into which the lung protrudes and occurs most commonly near the sternum or vertebrae through an intercostal space. The acquired type may follow an injury to any part of the chest wall the lung prolapsing through a defect produced by the trauma.

The usual symptoms are a bulging mass pain over the local area and cough. The size of the mass increases on coughing or straining. The cough is usually non productive but may produce bloody sputum. Incarceration and strangulation of these hernias have been reported.

Physical examination reveals a soft crepitant bulging mass which suddenly increases in size on coughing. A bony or fibrous rim may be felt through which a finger may be inserted into the chest cavity. The diagnosis is easily made.

Since these hernias rarely heal spontaneously treatment consists of freeing the contents of the hernial sac and closure of the defect in the chest wall by a plastic operation.

TUMORS

Various tumors of connective tissue origin such as lipoma, lymphangioma, hemangioma, osteoma and chondroma may develop in the chest wall. The most common is chondroma or osteochondroma which arises from a rib cartilage or the sternum. Many of these tumors are malignant especially those of a cartilaginous nature. Owing to the fact that most of them grow toward the pleural cavity they may reach a considerable size before producing symptoms or before their presence is discovered. The tumor frequently

arises at a costochondral junction and owing to its slow growth symptoms may be entirely lacking until adjacent structures are influenced by pressure. All structures of the chest wall are usually involved by the growth which is more or less spherical in shape, hard and nodular with areas of softening due to degeneration. Since metastases are rare the tumor is apt to be considered benign and differentiation is frequently difficult or impossible even on microscopic examination. Of 213 cases analyzed by Hed-

the tumor it can usually be filled in by the breast or scapula. Good results may be expected in the case of a benign lesion but recurrence is the rule following extirpation of a sarcomatous tumor.

A common malignant tumor described by Pancoast arises in the superior pulmonary sulcus. Although the source of development is questioned it is epithelial in nature and is likely bronchogenic in origin. This tumor gives rise to a characteristic clinical picture of pain in the shoulder, wasting of the mus-

Fig. 11—A 31 year old white woman entered the clinic complaining of some pain of several years duration beneath the right breast. There was slight dyspnea on exertion. On examination positive findings were limited to the right thorax which presented a large firm spherical tumor beneath the right breast extending from the second to the sixth rib. Roentgenograms of the chest revealed a spherical opacity occupying the lower two thirds of the right lung field. The tumor arose from the right fifth rib at a costochondral junction. It was removed en masse through a long incision over the entire length of the right fifth rib. Long segments of the fourth, fifth and sixth ribs together with the intercostal structures and parietal pleura were removed with the tumor. The defect left in the chest wall was closed by filling in with the scapula posteriorly and the right breast anteriorly. The patient made an uneventful convalescence and in seven years has had no evidence of recurrence. Microscopic sections revealed the tumor to be a chondroma.

blom (14 per cent) were sarcomas. In the absence of metastases differentiation between the benign and the malignant tumor is impossible before operation. They may also be confused with a dermoid cyst, cold abscess, aneurysm and exostosis.

Treatment consists in wide surgical excision. When the tumor is large no attempt should be made to preserve the underlying parietal pleura. Partial pressure anesthesia must be used for dealing with the surgical pneumothorax produced. If a large defect in the chest wall remains following removal of

cles of the hand and Horner's syndrome. Roentgenograms reveal a sharply defined opacity in the extreme apex of the pleural cavity with destruction of one or more of the first three ribs and at times the adjacent vertebrae. There is no known effective therapy.

Other malignant tumors frequently seen in the ribs are metastatic carcinoma from the breast and multiple myelomas. The latter are more easily detected here than in other bones.

WOUNDS OF THE THORACIC WALL, PLEURAL CAVITY, LUNGS AND MEDIASTINUM

General Consideration—The functioning of the cardiorespiratory mechanism is dependent upon certain anatomical and physiological facts that must be understood in order to evaluate the seriousness of various types of thoracic wounds and at the same time to make an accurate appraisal of the individual patient. For anatomical and physiological details reference must be made to standard textbooks on these subjects.

From an anatomical standpoint primary consideration must be given to the large number of thin walled arteries and veins that are present not only in the mediastinum and lungs but in the chest wall as well. Attention must be directed to the difference in pressure in the two arterial systems the peripheral and the pulmonary.

The method of arresting hemorrhage in thoracic wounds suffers with the type of blood vessel injured. If for instance a laceration of the lung causes hemorrhage from the pulmonary system owing to the low pressure in the pulmonary vessels resulting in the escape of blood into the thoracic cavity or hemothorax the bleeding can be arrested by compression of the lung whereas in an injury to the heart aorta or subclavian internal mammary or intercostal arteries hemorrhage into the pleural cavity or hemothorax may occur that will not subside following compression of the lung. Because the pressure in the systemic arterial system is high compared to that in the pulmonary system bleeding from the systemic arterial vessels will be much more vigorous than that from the pulmonary vessels. In case ligation of the pulmonary artery is necessary because of hemorrhage from the lung due to penetrating or perforating wounds it is well to know that the bronchial artery will supply a sufficient amount of arterial blood to prevent the lung from becoming necrotic or gangrenous. It must be noted that the pulmonary artery carries mainly venous

blood with a relatively low oxygen tension whereas the reverse is true of the bronchial artery. Cutting-off of the flow of blood from the pulmonary arterial system will therefore not affect the lung from a nutritional standpoint but of course will prevent its functioning from the standpoint of oxygenation of the blood brought to the lung. Circulation in the lung after ligation of the pulmonary artery is switched from an essentially venous circulation of relatively low oxygen tension to an arterial circulation with high oxygen tension. The development of the collateral circulation through the bronchial artery is rapid and extensive following ligation of the pulmonary artery.

Bleeding from venous structures that may be injured in wounds of the thorax must also be taken into consideration. These are the superior and inferior vena cavae and the innominate, axillary and hemiazygos intercostal and subclavian veins which may be considered the peripheral venous system. The arrest of hemorrhage from them presents a different problem from the control of bleeding from the pulmonary veins. Because of the vestigial character of the bronchial veins the blood must be carried away from the lung by way of the superior and inferior pulmonary veins. Therefore ligation of either of these will result in moist gangrene in the area of the lung which is drained by the ligated vein. If either the superior or the inferior pulmonary vein must be ligated because of injury it will be necessary to remove that part of the lung drained by that particular vein. This dual circulation of the lung must be borne in mind in the treatment of wounds of this organ.

Destruction or displacement of certain anatomical structures by injury interferes with the proper physiological function of the intrathoracic organs. The rigidity of the thoracic cage which is due to the anatomical integrity of the ribs and sternum is essential to the proper filling of the lungs during inspiration. This rigidity affords a purchase for the pull of the diaphragm and the intercostal muscles as well as the accessory muscles of respiration and maintains negative pressure within the thoracic or pleural cavity and as well within the air passages of the lung. Any interference with this rigidity permits collapse of the chest wall during inspiration owing to the contraction of the diaphragm. In addition to rigidity the thoracic wall must be intact for obviously a defect in the chest wall from an injury even though the rigidity in general is maintained allows the passage of air into the thoracic cavity and interferes with the proper filling of the lung because of loss of the normally present negative intrapleural pressure.

When air accumulates in the thoracic cavity there develops what is known as pneumothorax resulting in compression of the lung on the ipsilateral side and sometimes on the contralateral side. In addition to the direct effects of the loss of the negative intrapleural pressure on the filling of the lung with air there are other results of this loss which affect the normal physiological activity of the heart and therefore the cardiac output and blood circulation in general. The action of the thorax during inspiration with its effect on the filling of the right atrium is profoundly interfered with when there is disturbance of the delicate pressure balance within the pleural cavity. Serious effects

upon the general peripheral circulation may result therefrom. In dealing with perforating or penetrating wounds of the thoracic cavity, one must bear in mind the intimate relation between the anatomical and the physiologic aspects of the problem. Although general surgical principles are applied in the treatment of such wounds, due regard must be given to certain special aspects of thoracic wounds that set them apart from wounds of the head, abdomen and extremities.

Infection carried to the pleural cavity from a wound entering from within by way of the trachea or the esophagus will be discussed under the various types of wounds.

In view of experience, not only in civil practice but that which was reported from World War I and has been gained up to the present time in World War II it has been thought wise to consider the treatment of wounds of the thorax under the following headings: 1 *non penetrating wounds*; 2 *penetrating wounds*; 3 *perforating wounds*; 4 *combined pleuroabdominal wounds*; and 5 *concussion of lungs from blast injuries*.

Before discussion of these various injuries in detail it is well to note that there are certain fundamental principles pertaining to the treatment of thoracic injuries which must be observed in order to obtain the best results. In addition to the general surgical principles that are applied to the treatment of wounds elsewhere in the body, there are certain *first aid measures* that are essential if thoracic wounds are to be successfully treated. These measures are the arrest of hemorrhage from the thoracic wall, correction of disturbance of the cardiorespiratory physiology and prevention of infection. The arrest of hemorrhage from the thoracic wall is carried out according to well known general surgical principles. A sucking wound of the chest, the so-called sucking pneumothorax, which is due to a defect or an opening in the thoracic wall, requires an immediate airtight dressing and subsequent closure of the wound. So-called pressure pneumothorax or accumulations of air under pressure in the thoracic cavity must be provided with means of escape; this is accomplished by the use of a trap valve mechanism which allows air to escape but not to enter. Crushing injuries to the chest wall due to multiple fractures of the ribs or sternum associated with paradoxical respirations demand immediate external stabilization of the thoracic wall. This can usually

be accomplished by non operative methods such as strapping or external traction. Hemothorax or hemorrhage into the pleural cavity must be treated by aspiration with replacement by air or the establishment of an artificial pneumothorax. Hemorrhage which progresses in spite of collapse of the lung makes exploratory thoracotomy mandatory. Hemothorax due to hemorrhage into the pericardium resulting from wounds of the heart or large vessels within the pericardial sac should be relieved by aspiration until the nature of the wound is determined and facilities are obtained from exploration of the pericardium and heart.

Because of limitation of space, the general surgical measures employed for the treatment of all injuries such as debridement, chemotherapy, treatment of shock and administration of tetanus antitoxin and toxoid are purposely omitted from this discussion.

1 Non Penetrating Wounds of the Thorax—A wound which involves only the chest wall without opening the pleural cavity is termed a non penetrating thoracic wound. Such wounds are usually not associated with symptoms and signs referable to the pleural cavity or the cardiorespiratory system. There is unlikely to be hemoptysis, pleural effusion, hemothorax or disturbance of respiration. There may be some splinting of the side owing to local pain during the respiratory cycle. As a rule the management of such superficial wounds depends upon the cause. In a simple stab wound or bullet wound the treatment is conservative. If the wound is caused by a high explosive fragment it seems advisable to excise the wound. It should be remembered that such wounds of the posterior thoracic wall are more apt to result in deep infection than are those of the anterior wall. This fact is probably due to the greater likelihood that hematoma will be formed in the deep muscular layers posteriorly rather than anteriorly and will subsequently become infected. In some instances hemoptysis is present when the pleural cavity has not been perforated. This may be due to intrapulmonary hemorrhage as a result of concussion from non penetrating blows on the chest wall as seen in automobile accidents or as a result of simple fracture of one or more ribs from a fall in which the ribs have penetrated the

wound to a large defect in the thoracic wall as the result of a high explosive missile. The signs and symptoms of course vary in direct proportion to the extent of the injury. In a simple stab wound or gunshot wound which punctures the pleural cavity but does not cause serious hemorrhage and shock only some local pain the patient may even be unaware of the presence of the wound. Such simple penetrating injuries are practically asymptomatic and treatment is always conservative unless a foreign body is found in the thoracic cavity as a result of roentgenographic study. In such a case one should always suspect that other foreign bodies may have been carried into the pleural cavity with the penetrating fragment such as portions of the clothing. It is probably wise to excise the wound of entrance perform a thoracotomy remove all foreign bodies close the wound and observe the patient for possible infection.

If however the penetrating injury severs a peripheral artery such as an intercostal the internal mammary or the subclavian artery or on the other hand one of the major pulmonary vessels near the hilus or the azygos vein associated with the injury there will be bleeding into the pleural cavity resulting in hemothorax and attended by a certain degree of shock. The bleeding will be slow or brisk depending on the size of the injured vessel. If however an intercostal vessel is severed without laceration of the lung hemothorax may be present without expectoration of blood. The hemothorax will progress but not so rapidly as it will from an injury to the internal mammary or subclavian artery. Often the wound of entrance gives a clue to the possible source of the bleeding. In the case of injury of the internal mammary artery the anatomical location of the entrance wound is about 1 cm. lateral to the sternal border. A bleeding wound in this region at once suggests injury to this vessel particularly if there is hemothorax without hemoptysis. Again a wound of entrance near the dome of the chest in the region of the subclavian vessel suggests the possibility of a hemothorax originating from this wound. More frequently however there is associated with such penetrating injuries a concomitant laceration of the lung from which there arises

bleeding in the pleural cavity and in the veins resulting not only in hemoptysis but also in hemothorax from the lacerated lung as well as from the peripheral vessels. In other words there is bleeding from both the pulmonary and the peripheral arterial system. In most instances however only a laceration of the lung results from a penetrating injury. Furthermore lacerations of the lung differ in extent. A peripheral laceration bleeds less rapidly and vigorously than does a laceration of the hilum. Again the wound of entrance and the probable course of the penetrating body aid in determining the severity and nature of the intrathoracic wound.

In all of these cases treatment consists of first aid for shock with administration of blood or plasma as well as administration of morphine and the patient must be placed under close observation. No set rule can be given for the definitive treatment.

Small penetrating wounds such as bullet wounds which do not admit air are usually treated conservatively particularly if there is reason to believe that only laceration of the lung has occurred. If however because of recurring hemoptysis in the presence of artificially produced pneumothorax there is reason to believe that the bleeding persists in spite of the collapse of the lung thoracotomy should be performed immediately search made for the bleeding vessel and ligation carried out. As mentioned previously hemothorax that persists and recurs after repeated thoracenteses and after the injection of air has produced collapse of the lung must be regarded as arising not from the pulmonary circulation but from the peripheral circulation, and unless the bleeding is arrested the patient will bleed to death within his own pleural cavity. If in addition the penetrating wound has produced a large defect in the thoracic wall the diameter of which is larger than that of the trachea there results a sucking pneumothorax which necessitates immediate air tight closure. The larger the defect the more urgent the necessity for preventing aspiration of air. The sequelae of such a sucking pneumothorax have been discussed. The patient should be treated immediately for shock in the usual manner with mild sedation such as a small dose of morphine. The

opening in the chest wall should be closed immediately as an emergency measure with any dressing that is at hand such as adhesive tape or petrolatum gauze. If the wound is extensive such as those made by irregular fragments careful debridement of the skin and muscles must be done. The thoracic cavity should be cleaned out thoroughly and all foreign bodies removed. If laceration of the lung is present this should be repaired either by direct stitching or by transfixing the lacerated edges. In some instances it may be necessary to perform lobectomy; however this procedure should be reserved for the most serious tears and lacerations. It should be carried out under general anesthesia with intratracheal insufflation or a very tight fitting mask so that differential pressure may be maintained. Closure of the defect in the thoracic wall is essential and can be accomplished by the use of pedicle flaps of muscle from the pectoral group or the latissimus dorsi and also by crushing the phrenic nerve (either in the neck or trans thoracically) from the immobilized diaphragm. Occasionally it is advisable to stitch the damaged lobe of the lung into the defect so as to fill the opening into the pleural cavity. In some cases it is possible to cover the defect with skin. Drainage by water seal catheter should be instituted and the patient should be carefully observed for the development of empyema. It is advisable to administer oxygen as soon as possible.

It is well to remember that one or all of the combinations of injuries to the various organs occur with penetrating wounds. In all probability each case will be different and must be considered individually. Sometimes pressure pneumothorax develops from a penetrating injury that produces laceration of the lung or from injury to one of the primary bronchi or the trachea. Because of the absence of an avenue of escape the intrapleural pressure increases to the point where labored respirations and greater dyspnea are produced with dislocation of the mediastinal contents towards the uninjured side. The thoracic cavity on the uninjured side should be punctured in the second interspace anteriorly with a 15 or 20 gauge needle which may be attached either to a water seal catheter or to a perforated finger cot so that air may escape from the pleural

cavity but cannot be sucked back into it. If this method of treatment is insufficient to overcome the increased pressure either the thoracotomy with closure of the defect in the trachea or bronchus and stitching of the lacerated lung or lobectomy is advisable. If the defect in the bronchus or the trachea is of sufficient size to prevent closure of the wound by suturing a small patch of parietal pleura can be sutured as a transplant or pedicle flap across the defect.

If injury to the esophagus is present this structure should be repaired by direct suture. It is usually possible to mobilize the esophagus sufficiently to bring the lips of the defect together. Suture of the esophagus should be done with interrupted silk sutures in the mucosa which is the most useful layer available for sewing. The muscular layers should then be brought over the mucosal sutures. The mediastinal pleura in that region should be allowed to remain open so that if there is infection it will drain into the pleural cavity. After the proper use of chemotherapy the thorax should be drained by means of a water sealed catheter.

Injuries of the esophagus or the trachea are usually associated with mediastinal emphysema which can be detected primarily by crepitation in the suprasternal notch. If the course of the penetrating missile seems to demand it the esophagus should be explored.

In thoracic injuries it is preferable to explore the esophagus through the thorax rather than through the posterior mediastinum for this approach enables the operator not only to explore the thoracic cavity but to examine the lung and adjacent structures as well.

Penetrating injuries associated with wounds of the heart may occur with or without communication between the pericardial and pleural cavities. If there is no communication there is usually massive intrapleural hemorrhage and the patient rarely survives long enough to be hospitalized. However in case operation is resorted to the approach should be transthoracic with aspiration of blood from the chest and pericardial cavity and an attempt should be made to suture the wound in the heart or the great vessels emerging from the heart.

In case of injury to the heart in which

there is no communication between the pericardial and pleural cavities bleeding into the pericardial sac results in pressure upon the heart or cardiac tamponade. This is clinically manifested by peripheral circulatory collapse distended veins of the neck with great increase in venous pressure small pulse pressure muffled heart sounds and an immobile cardiac shadow on fluoroscopic examination. The pericardial sac should be aspirated by the costophrenoid route and if the tamponade persists or recurs after several aspirations the heart should be exposed extrapleurally and cardiorrhaphy or suturing of the wound of the heart performed.

3 Perforating Injuries of the Thorax.—Perforating injuries of the thorax are those in which the foreign body has completely traversed the thorax causing a wound of entrance and a wound of exit. The patient is usually very little disturbed from the clinical standpoint. After treatment for shock and the usual rehabilitation therapeutic procedures such as sedation and rest the patient should be examined by x-ray if the roentgenogram reveals retained foreign particles within the lung or thoracic cavity these should be removed. In other respects perforating injuries of the thorax are treated in the same manner as penetrating wounds.

4 Pleuroabdominal Wounds.—Transdiaphragmatic injuries or rupture of the diaphragm are, as a rule, the result of a crushing injury to the chest or abdomen or both. There are severe epigastric pains a persistent hyperresonant percussion note at the left base and distant and diminished breath sounds. The posterior portion of the left side of the diaphragm is usually injured and a diagnosis of such an injury can be made in almost every instance roentgenographically. Various portions of the abdominal viscera may have ascended into the thoracic cavity. Rupture of the right side of the diaphragm is more uncommon than that of the left but in the event that this has occurred a portion of the right lobe of the liver may be found in the thoracic cavity. A combined thoracoabdominal incision should be made in the ninth interspace with exposure of the upper right or left quadrant depending upon the individual case. General anesthesia must be used with differential pressure maintained by tracheal insufflation or a tight

mask. Injuries of the abdominal viscera or lung are treated according to their type. The diaphragm is sutured after the abdominal viscera have been returned to the peritoneal cavity.

5 Concussion of the Lung.—Concussion of the lung following blast injuries or impacts by pressure waves from high explosives at close range sometimes causes extensive damage to the lung without evidence of external injury. Such an injury is associated with profound shock cough hemoptysis of varying degree dyspnea and cyanosis. Roentgenographic study of the chest may not be helpful for the first few days after the injury. Autopsies in Britain during the period of the heavy bombing of London showed the lesion to be an intrapulmonary hemorrhage varying from petechiae to large ecchymotic areas.

Treatment includes rest administration of oxygen and sedation. If concurrent injuries to the body necessitate the use of anesthesia local intravenous or spinal anesthesia should be employed rather than an inhalation type.

WILLIAM F. RICHMOND, JR.

SURGERY OF THE PLEURA

Anatomy.—The parietal pleura is separated from the chest wall by the endothoracic fascia. The normal pleura is so thin that the most delicate dissection is necessary to avulse it. It often tears spontaneously after being detached from the endothoracic fascia. It is so frail that it is useless to try to suture it since the stitches tear through. The costal portion of the pleura is closely attached to the chest wall except at the apex where lesser strands fix it to the prevertebral fascia. The mediastinal pleura is also loosely attached but all of the visceral pleura is completely fastened to the underlying structures.

In the loose spaces of the endothoracic fascia runs a rich network of lymph spaces. Lymph nodes and a series of intercostal glands. By injecting salt solution or a alkali solution of procaine into these meshes even the glomerular process of the pleura can be separated from the chest wall and protected from tearing during resection.

The topography of the pleura is apparent from the accompanying diagram. The lungs do not quite reach the edge of the pleural cavity; there is a reserve space at the bottom of the chest at which safely broad surfaces of the lymphatic and the costal portions of the pleura are in contact. On inspiration this space is compressed but never not even on maximum inflation.

does the lung quite fill it. Free pleural exudates naturally gravitate toward this sinus and force the pleural layers apart, subdiaphragmatic effusions and shrinking intrathoracic processes that lift the diaphragm bring the diaphragmatic and costal portion of the pleura into broader apposition, increasing the depth of the sinuses. Both the normal and the abnormal topography of the complementary sinuses are therefore of much importance in calculating the sites of proposed openings into the chest. It is also noteworthy that the pleural reflection, *i. e.*, the bottom of the complementary sinus, does not quite reach the diaphragmatic insertion but that there is a small triangular area between the diaphragm and the chest wall filled with loose endothoracic fascia or with fat through which the diaphragm may be reached from above without traversing the pleura. By a properly placed incision therefore, one may gain access to the upper surface of the diaphragm lift up the pleural sac without entering it and even make a transdiaphragmatic laparotomy without opening the pleura. This procedure is more easily earned out when the pleura is thickened and inflamed than when it is normal.

Fig. 472.—Topography of the pleura and complementary sinuses (Redrawn after Corning)

The topography of the visceral portion of the pleura also merits detailed study, for while the visceral covering of the pulmonary surface is comparatively simple, the interlobar fissures into which the pleura dips present complicated relations. Collections of fluid encapsulated between the layers of the interlobar pleura may give rise to roentgenographic shadows that are difficult to interpret.¹

Physiology.—(See section on Mechanics of Respiration.)

INJURIES OF THE PLEURA

Traumatic Pleurisy.—Traumatic pleurisy is a common ailment. Blunt violence or contusion of the chest wall may set up a painful, localized pleurisy, often with a bloody fibrinous deposit. Coexistent syphilis may give rise to massive, bloody effusion out of all proportion to the inciting injury. Pleu-

ris regularly accompanies fracture of ribs, and the pain may last many weeks. The exudate is partly absorbed and partly organized, adhesions often form at the site of injury and occasionally, perhaps as the result of superimposed infections, the pleura thickens so that the chest wall is lined with a casing resembling a bacon rind. Local tenderness to pressure in the intercostal spaces, spasm and immobility of a portion of the chest wall, with dullness to percussion, diminution of breath sounds, a pleural friction rub and a more or less pronounced area of increased x-ray density, give evidence of such a pleurisy. Strapping a wide area of the hemothorax with elastic adhesive plaster and allowing the patient to lie on the affected side, a position which he naturally assumes will give relief. If pain persists, blistering or

painting the chest with several coats of tincture of iodine are old-fashioned remedies that are often useful. The intercostal neuralgia or neuritis may be severe and obstinate enough to call for posterior rhizotomy.

Injuries of the Pleura.—(See sections on Traumatic Emphysema, Pneumothorax and Hemothorax.)

Pneumothorax.—(See sections on Pneumothorax.)

Hemothorax.—(See section on Hemothorax.)

Hydrothorax.—*Serous effusion* into the chest, whether a dropsical transudate of low specific gravity (less than 1.015) or an inflammatory exudate of higher specific gravity, may be tapped if necessary but should not be treated by open drainage. The incal-

culable harm that results from this ill advised procedure makes it seem wise to sound this warning in a surgical text.

Chylothorax—Chylothorax results from intrathoracic injuries to the thoracic duct or from disease causing damage to the duct. Leaks in the lower part of the duct usually cause right sided chylothorax. Leaks in the upper part cause a left sided one. Treatment is by aspiration.

INFLAMMATION OF THE PLEURA

Inflammatory disease of the pleura surgically considered is always secondary. It may be dry and fibrinous (adhesive or obliterative pleurisy) as in the traumatic pleurisy just described, serous (the usual tuberculous pleurisy), sanguinolent (tuberculous or carcinomatous pleurisy) or purulent (suppurative pleurisy, empyema thoracis). The infectious agent may reach the pleura directly as in an infected penetrating wound or a ruptured lung abscess by continuity via the lymphatic channels from the most varied inflammatory disease of the neighboring structures as in acute pleurisy and empyema associated with pneumonia, subdiaphragmatic abscesses, osteomyelitis of the ribs and vertebral bodies etc. and finally and rarely via the blood stream as part of the picture of pyemia. Most cases of acute empyema encountered in civil life are metapneumonic or postpneumonic.

ACUTE SUPPURATIVE PLEURITIS (ACUTE EMPYEMA)

Pathology—An early acute inflammatory exudate is serous but may be more or less turbid. It is usually odorless but in putrid infections it may be extremely foul while still quite clear. It has a high specific gravity (more than 1.015) microscopically it contains polymorphonuclear leukocytes in various stages of development and degeneration and a small proportion of lymphocytes and endothelial cells. It may or may not contain bacteria demonstrable by smear or culture. Some pleuritic exudation regularly accompanies adjacent inflammatory disease. The pleura itself seen in these early stages is thickened, red, inflamed and no longer glistening. Later if the exudative pleurisy goes on to suppuration the exudate becomes more turbid, opaque, milky, creamy or more

or less bloody. Thick yellow pus is usually homogeneous, the thinner less opaque effusions are often mixed with large flakes, shreds and curds of coagulated fibrin. Such pus contains large numbers of leukocytes with nuclear debris. The pleura is thickened, edematous and succulent and beset with shaggy tufts of fibrinous deposit. Organisms are usually demonstrable in the pus by smear and culture: streptococci and pneumococci are the most frequent offenders, more rarely staphylococci and in fulminating putrid infection there is a mixed putrefactive flora. Pneumococci predominate in empyema in children while streptococci are usually found in adults. The epidemic empyemas following epidemics of measles, influenza and epidemic bronchopneumonia are streptococcal. Tuberculosis is strongly to be suspected if no organisms can be demonstrated in the pus. In empyema the chest at times contains not only pus but air or gas which may come either from a perforating pulmonary suppuration communicating with the bronchial tree or from the presence of gas forming microbes.

The exudate may lie free in the pleural space collecting in the dependent portions of the chest or if an adhesive pleurisy has preceded exudation the fluid may be confined by adhesions to certain characteristic locations. Thus we speak of interlobar empyema when the pus lies confined in an interlobar fissure such as in empyema owing to its proximity to the larger bronchi is usually liable to perforate into the lung. A mediastinal empyema lies confined medially between the lung and the mediastinum. A diaphragmatic empyema lies between the lung and the diaphragm.

Symptoms and Course.—The graphic chart of an ordinary postbronchopneumonic empyema has a characteristic appearance. The pneumonic fever has abated, the temperature, pulse and respiratory rate and leukocyte count have dropped but not to normal. After a week or so of a subfebrile course the temperature again rises and the patient begins to lose weight and strength. He sweats, he has difficulty in breathing and he has pain or a sense of oppression in the chest. Expectoration diminishes but not the cough which is irritating and nonproductive. The affected side lags or stands still on

respiration the intercostal spaces bulge especially in weakly children they are moderately tender to pressure over the lower parts of the chest The heart and mediastinum are crowded toward the unaffected side The lower part of the chest is solidly dull and the upper part somewhat hyperresonant over the flat area breath sounds are missing above it breathing may be tubular or vesicular and distant farther up there may be the loud sharp breathing of a compressed useless lung Administration of sulfonamide drugs in pneumonia probably tends to prevent empyema but it also tends to mask its presence Fever and the ordinary constitutional symptoms of toxicity may be wanting still the chest may be full of pus

F^o 473—Roentgenogram of right-sided basal effusion

Diagnosis.—An x-ray film which should be taken with the patient sitting or standing demonstrates a curved shadow obscuring the lower part of the chest its outer portion running upward along the chest wall it also corroborates the clinically manifest displacement of the heart and mediastinum The film may show patches of bronchopneumonic consolidation here or there perhaps on the opposite side or what is more important evidence of recent or obsolete tuberculosis in the apices a pericardial effusion or other complications which should be ascertained before treatment is begun Films of a recumbent patient are almost valueless the boundaries of a free effusion and disease of the underlying lung are indistinguishable in such a picture If the patient

cannot sit up he should be placed first on one side then on the other and an anteroposterior roentgenogram should be made in each position so that the fluid may gravitate toward the lateral or medial side of the chest

b Aspiration (thoracentesis) is necessary and helpful even though a roentgenogram is at hand However it is not entirely harmless The utmost care should be taken not to puncture the lung especially when the patient is coughing constantly for one may be sure that if the effusion is not purulent when the lung is punctured it will become so afterward Simple puncture of the chest wall and pleura in such a case is not entirely harmless either the violent increase of intrathoracic pressure that accompanies severe fits of coughing may force infectious material from a virulently infected pleura into the loose spaces between the thoracic musculature giving rise to phlegmons more serious and difficult to deal with than the empyema for which puncture was done For these reasons therefore it is wise to make provision for immediate drainage at the site of puncture if pus is found or else if operation is not contemplated or seems inappropriate to defer puncture

It should be remembered that physical and roentgenologic signs of atelectasis may closely resemble those of an effusion If the density does not shift with changes in the patient's position and if the mediastinal viscera are retracted toward the affected side aspiration should be undertaken if at all only with considerable misgiving and after due deliberation

With these preliminary precautions and several well fitting glass syringes with a number of well fitting clean needles procaine solution, water culture tubes and containers are sterilized and after injection of a local anesthetic into the chest wall a no. 19 gauge 6 inch needle is slowly introduced into the pleura across the top of a rib at a site where local tenderness, bulging of the intercostal spaces and flatness indicate the presence of fluid A small bore 10 to 15 cc syringe should be used for exploration large syringes impart the danger of sensation As much pus as can be conveniently aspirated is removed, and cultures and smears are made

Only if the smears demonstrate organisms and polymuclear white cells it is permissible to proceed with rib resection The absence of organisms usually means that tuberculo-

sis is present and to treat a tuberculous empyema by open drainage is as Ciot said of other cold abscesses "to open the door whereby death enters" If the first exploration fails to demonstrate pus, puncture may be repeated elsewhere.

Treatment.—An acute empyema having been demonstrated the question of treatment arises. Decision is not always easy. Open rib resection and drainage are disastrous to a patient still suffering from severe pneumonia or its immediate toxic after effects. The mortality of early rib resection during the influenza epidemic of 1918 was from 40 to 90 per cent. Increased respiratory

tensor axillary line and the line of the scapular angle (provided exploratory puncture has demonstrated pus at this site of election). A large trocar and cannula are thrust into the chest through the scalp puncture the trocar is withdrawn and a stiff rubber catheter (no 18 or 20 F) rapidly substituted for the trocar. The cannula is withdrawn leaving the catheter in the chest as an air tight drain. Before beginning operation one should make sure that the catheter fits the cannula. The catheter should have two eyes about 1 inch apart. It should be marked at the point which is to correspond to the skin level before it is inserted so that its openings lie near or at the bottom of the chest. If it is pushed in too far it will not drain properly. Catheter drainage has the advantage of allowing the fluid to drain slowly and continuously under its own pressure and to be less liable to be plugged with blood or fibrin than a pump apparatus. The

Fig 474—Diagram showing introduction of the catheter into the pleural cavity in the closed method of treating empyema. a The trocar is passed through the thoracic wall. b The obturator of the trocar has been withdrawn and the catheter inserted through the trocar which is then being withdrawn.

difficulty and pain flapping about of the acutely pneumonic lung and increased absorption from the freshly opened pleural cavity all tend to contribute to the fatal outcome of early open operation. In an acutely toxic patient with high fever, emaciation and distressing dyspnea the chest should be emptied of fluid either by aspiration or by intercostal siphon drainage.

If aspiration is decided on, a large gauge needle is inserted into the chest and the fluid aspirated with a large glass syringe or pumped out with a vacuum bottle (Potam aspirator). Aspiration is repeated as the fluid reaccumulates usually every three or four days. Siphon drainage is probably better and is carried out as follows:

Under local anesthesia and with the patient propped up in bed in a sitting position a pointed scalpel is thrust into the skin and soft parts over the seventh or eighth intercostal space half way between the pos-

catheter is connected to a sterile rubber tube immersed in a bottle of antiseptic solution placed on the floor at the bedside. It should be held in accurate position with a snug small rubber collar sewed to the skin with a single stitch.

The fluid of a virulent streptococcal empyema is usually turbid, thin and bloody and contains little fibrin at first, it usually runs out easily, later it becomes thicker and greenish and contains large clots of fibrin. At this stage the cavity may be irrigated with Dakin's solution which has the property of dissolving fibrin. If a sufficiently intelligent assistant is at hand the irrigation may be accomplished with a hand syringe; if not one of the many apparatuses for tidal irrigations may be used. Occasionally in pneumococcal empyemas of children (18 per cent) more rarely in empyemas of adult age (11 to 13 per cent) aspiration or intercostal siphon drainage with irrigation is all

that is necessary to effect a cure. Ordinarily the exudate becomes less and less serous and thicker aspiration gives a scanty yield the cannula no longer fits securely pus leaks around it and the empyema becomes subacute. At this time the chest should be efficiently opened by resection of a rib. Sulfonamide drugs administered by mouth and used in solution to irrigate the empyema cavity may increase the percentage of cures by aspiration and closed drainage methods and may lessen the need for rib resection. Irrigations with sulfonamides produce high drug concentrations in the pleural fluid with little absorption into the blood stream absorption drops and local concentration rises as the empyema grows older and the pleura thickens. Recent reports indicate that penicillin is even more efficacious especially in staphylococcal empyema. Through an intercostal catheter 30 000 to 100 000 units should be instilled into the chest and allowed to remain for eight to twelve hours. After this the solution should be drained off and replaced by a fresh amount. The drug may be administered intramuscularly or intravenously at the same time.

Rib resection and open drainage are carried out as follows:

With the patient propped up in a sitting position the skin the soft parts and the intercostal spaces above and below the eighth rib in the posterior axillary line are infiltrated with novocain the soft parts including the periosteum are incised over the rib the periosteum is detached and 1/2 or 2 inches of rib is resected. The underlying intercostal nerve is injected with 0.5 cc of absolute alcohol to prevent pain from the pressure of a drainage tube and the posterior costal periosteum with the subjacent pleura is incised. Large free curds of fibrin are removed by suction or with a sponge holder. Attempts to clean the pleura by rubbing it with gauze or otherwise maltreating it are purposeless. A large moderately soft rubber drain about 1 inch in diameter with one or two openings cut into one end and with a soft Penrose drain or a slit finger-cot tied over the other end to act as a valve is inserted for 2 or 3 inches into the chest and securely held in this position by sewing it to one edge of the skin with a loose stitch of silk-worm gut. Loose iodoform gauze packing is inserted into the soft parts which are not sutured about the drain but left entirely open. Irrigation of the chest has but little purpose after rib resection for once the thorax is efficiently open it is impossible to reach all the pleural cavity with irrigating solutions. They merely puddle in the bottom of the chest and keep the patient wet and uncomfortable.

Drainage is means of a skin flap without the use

of tubes has proved especially useful in military hospitals and other situations where a minimum of after-care is possible. A U-shaped flap of skin and subcutis is turned up its base lying at the level of the rib which is to be resected. The rib is resected together with its pericostea. The skin flap is tucked into the opening and its corners are attached to the pleura with two catgut sutures. The flap forms a valve through which it is easier for the contents of the chest to escape than it is for air to enter. A liberal dressing of petrolatum is left undisturbed for many days the outer dressings being changed as necessary. The empyema heals with a minimum of attention and without the irritation and discomfort of a rubber tube.

Theoretically it is hard to understand how an empyema cavity treated by rib resection with an opening in the chest wall the diameter of which exceeds the diameter of the glottis should ever heal. It would seem easier for the act of inspiration to suck air through this opening than through the glottis thereby causing a lesser pressure inside the lung than outside and maintaining the lung in a state of permanent collapse. Yet experience shows that this theory does not hold and that drained empyemas do heal. The fact is explained by the following considerations: (1) The wound is never perfectly open but is partially occluded by dressings which act as a valve making it easier for air to escape from the chest than enter into it. (2) Each rise in intrapulmonary pressure above atmospheric pressure especially coughing talking or any expiratory effort against a closed glottis forces air from the inflated lung into the collapsed one dilating it. (3) Unless bound down by some shrinking intrapulmonary disease the healthy lung tends inexorably to expand adhering a little further to the chest wall until it finally fills the whole thoracic cage.

It is quite possible that recent experiences in military hospitals may revolutionize the treatment of acute empyema especially of the traumatic variety following infected hemothorax. The methods under trial include liberal transfusion of whole blood and plasma use of penicillin locally and intravenously wide thoractomy under intratracheal anesthesia decortication stripping of inflammatory products from the visceral pleura immediate insufflation and reexpansion of the lung and closure of the chest with a tight intercostal drainage. Drainage is used merely to take care of post-operative effusion the drainage tubes are well drawn in a few days.

Varieties of Acute Empyema—It remains to discuss some varieties of acute empyema which from their course or localization present certain peculiarities. Epidemic empyemas seem to have certain characteristics that remain constant in each epidemic but vary from one epidemic to another. Thus the empyemas of the 1917-18 war-camp epidemic of influenza and upper respiratory infection were characterized by extreme prostration deep cyanosis and dyspnea high fever and high pulse and respiratory rates.

The effusions were large and consisted at first of a thin turbid sero-sanguineous effusion often with a putrid odor which was especially pronounced in the empyema following measles pneumonia.

This type of empyema appeared early in the course of a sudden diffuse patchy bronchopneumonia although the patients frequently told of an ambulatory respiratory infection a cold with some fever and malaise lasting about two weeks to which they had given little attention. Massive effusion became apparent early three to five days after the onset of pneumonia while the temperature was still high there being no free febrile interval between the pneumonia and the empyema.

The metapneumonic empyema described by older observers following lobar pneumonia a week or ten days after defervescence was characterized by an encapsulated collection of thick creamy pneumococci causing fever and sweats but not cyanosis or severe prostration and having a fairly low mortality. This type however has become less frequent than the more fulminating form just depicted.

Most fatal is the empyema caused by the sudden rupture of an abscess into a defenseless virgin pleural cavity. The overwhelming onslaught is comparable to that of a fulminating diffuse peritonitis from a ruptured bowel. A rapid thready pulse delirium great prostration cyanosis and dyspnea are noted. The temperature and leukocyte count are usually high but both may be low. If a ruptured lung abscess or a ruptured secondarily infected tuberculous cavity is at fault the thorax may contain a small amount of foul turbid fluid surmounted by a large amount of air under pressure. In these dangerous fulminating pleuritis large doses of sulfonamides orally should be of especial value and likewise penicillin both instilled into the pleura and administered intravenously or intramuscularly.

Putrid empyemas containing gas forming anaerobes belong to this category. It is likely that small cortical pulmonary abscesses or patches of lung gangrene underlie them for it is difficult to understand how anaerobes which are not blood borne organisms could reach the pleura otherwise. Comparatively innocent localized although

excessively foul empyemas of this kind are not infrequently seen in the aged.

Every pyopneumothorax no matter how unheralded its onset must be regarded as tuberculous until proved otherwise for the commonest cause of this accident is the rupture of a tuberculous pulmonary cavity. The aspirated pus and the sputum as well should be examined for tubercle bacilli and the x-ray plate should be scrutinized for evidences of tuberculous in both sides of the chest. All of these fulminating forms of empyema many of which contain gas and pus under much pressure should be treated by intercostal trocar drainage.

Encapsulated empyemas occupy a midposition between the acute and chronic forms. They occur if the suppuration has been preceded by a dry adhesive pleurisy or if the pleura has suffered recurrent inflammatory attacks. Diaphragmatic mediastinal and interlobar collections especially those encapsulated deep in the interlobar fissures far from the costal pleura may be difficult to recognize and extremely difficult to differentiate from a consolidated or less lobe of the lung. Prolonged observation outlining the lung under the x-ray with opaque oil injected into the bronchi and the aspirating needle will usually identify them sooner or later. Small localized collections may often be needled to advantage under the guidance of a fluoroscopic screen they should be drained by an accurately placed rib resection. Great care should be taken not to open the unaffected pleura the pocket should be entered with an aspirating needle after the rib has been resected and the needle should be followed by a knife or a canter. The opening should be drained by a large rubber tube. If after the rib has been resected the encapsulated pus collection can no longer be encountered operation should be stopped before the pleura is entered and the wound should be packed. It is not legitimate to enter the unaffected pleura with the idea of exploring for an abscess for it is entirely likely that one or both of two disasters will happen either that adhesions holding the lung to the costal pleura will part and allow the lung (and with it the pus contained between its lobes) to retreat to inaccessible depths or that the localized empyema will rupture into the previously uninfected and

defenseless free pleural cavity. If the operation is stopped and the wound packed adhesions will form that may allow the abscess to be opened later with safety.

Effusions in the neighborhood of acute inflammatory processes usually begin as serous exudates and may remain so they may however go on to suppuration they are often more or less encapsulated such diaphragmatic pleuritis more or less regularly accompany subphrenic abscess amebic abscess of the liver and abscess of the spleen the lymphatic current flowing from below the diaphragm upward. These basal empyemas may mask the underlying subphrenic suppuration and make its recognition difficult. They may at times be drained to

eign bodies especially lost or forgotten drainage tubes and gauze in neighboring foci such as osteomyelitic ribs which continue to discharge pus into the pleural cavity or in bronchial fistulas the openings of which may be imperceptibly small. Finally underlying chronic disease of the lung prevents its reexpansion to fill the pleural cavity.

Unrecognized empyemas may discharge spontaneously (empyema necessitatis). An abscess bulges usually in the lower portion of the chest near the sternum and either perforates or is incised discharging an amount of pus which incredibly copious though it may be is rarely copious enough to effect a cure.

gether with the underlying abscess by an incision which enters the pleura traverses the diaphragm and ends in the subdiaphragmatic space. Similar effusions may collect around osteomyelitic vertebral bodies or ribs and other foci of suppuration.

CHRONIC PLEURISY AND CHRONIC EMPYEMA

An empyema is or becomes chronic for four reasons: 1. It has not been recognized and treated. 2. The infecting organism is of a kind that in itself causes chronic suppuration e.g. the tubercle bacillus actinomycetes etc. 3. There is a local cause for chronicity which is to be sought in an unextinguished focus of suppuration. Such local causes may lie in a partially sealed off pocket of pus within the pleura itself in for-

The pleura of a chronic empyema becomes thicker and harder and more melastic as time goes on. It may be an inch or more thick. It crunches under the knife. It has no toughness and stitches cut through it as they would through a raw potato. It has no blood supply and does not bleed when cut. The thickening affects mainly the costal pleura, much less the visceral one, so that while the costal pleura may be an inch thick the lung may be covered by no more than $\frac{1}{8}$ inch of thickened pleura. The thickening, hardening and inelasticity explain the shrinkage and rigidity of the chest wall that accompany chronic empyema. They explain the distortion not only of the mediastinal viscera but of the whole torso, the scoliosis and also the porosity of the ribs which

immured in such a encrass atrophy from disuse Occasionally these thick pleural crassings are lined with large thin chalky plaques which beset them like oyster shells rarely they contain true deposits of bone between their layers Chalky plaques are found most frequently in chronic empyemas of the aged In tuberculous empyema the pleura may be lined with typical epitheloid tubercles ordinarily these old thick pleuras are almost devoid of cellular elements

There is one type of *chronic proliferative pleurisy* without exudation and without suppuration which is more of pathologic than clinical interest Except over the pulmonary apices where it often accompanies an old fibrous tuberculosis it is rare when extensive it may cause scoliosis and other deformities of the trunk Syphilis may produce such a type

Recognition of the underlying cause of chronicity may be difficult not only the pus but sections of the pleura should be examined

Chronic Pyogenic Empyema—Chronic pyogenic empyema often causes recurrent attacks of fever the patient is pale and emaciated and has much the appearance of a phthisic a small sinus or a tiny drainage tube often discharges profusely the chest as may be expected from the description of the pleura is shrunken and distorted and does not move on respiration The x-ray picture discloses a massive density in which films of higher penetration may reveal cavities with a fluid level or faint shadows of calcification or of foreign bodies If one is fortunate enough to find a curable focus of suppuration a loose foreign body or a half sealed off pocket which can be drained efficiently the apparently most hopeless empyema may heal the heavy fibrous pleural thickening may be absorbed and the chest may regain its mobility If small recurrent bronchial fistulas cannot be closed they may be shut off from the pleura by packing and brought to the surface through a properly placed rib resection (marsupialized) If all efforts fail thorough mobilization of the chest wall by a series of extensive rib resections which lay the infected cavity and all its overhanging edges wide open will usually bring the infection to an end after which the wound may be closed by a plastic operation

These operations are difficult and entail considerable risk Fresh air sun baths and a liberal diet high in proteins and vitamins aid greatly in overcoming the effects of chronic suppuration

Tuberculous Empyema—Most primarily chronic empyemas are tuberculous Tuberculous empyema may be divided into two categories uncomplicated sterile tuberculous empyemas and secondarily infected ones The incidence of both forms has risen greatly since therapeutic pneumothorax has come into common use The incidence of purulent effusion in artificial pneumothorax is given variously at from 6 to 41 per cent The frequency of tuberculous empyema therefore is apparent when one considers that there are many thousands of tuberculous patients in the United States alone who are receiving pneumothorax Tuberculous empyema may be primary or secondary to pulmonary tuberculosis In the so called primary form a hidden focus may be found in suppurating caseous mediastinal lymph nodes which have broken through into the pleura

Symptoms of the disease vary greatly some patients may harbor a large effusion and complain of nothing but moderate dyspnea or fullness in the chest others have a high temperature and drenching sweats and are profoundly toxic The signs are those of a pleural effusion pulmonary involvement may be entirely absent In febrile patients it may be difficult or impossible immediately to distinguish between tuberculous and ordinary acute suppurative empyema yet the diagnosis is of paramount importance for to treat a tuberculous empyema by open drainage is usually fatal The most important factor in arriving at a diagnosis is to think of the possibility of tuberculosis Pus mixed with clots of fibrin with no organisms demonstrable by smear or culture is always highly suggestive of tuberculosis The pus may contain myriads of acid fast bacilli more often none can be demonstrated in a smear When in doubt it is usually wise to await the results of guinea pig inoculation or culture for tubercle bacilli

Treatment of uninfected tuberculous empyema is still under dispute In some cases spontaneous healing is obtained with simple rest in bed and proper hygienic measures

The amount of the effusion may demand aspiration but repeated aspiration usually leads to secondary infection. Substitution of the tuberculous pus with antiseptic oil (oleothorax) has led to cure. Persistently toxic febrile patients have been cured by a flap operation as described in the section on treatment of acute empyema.

Secondarily infected tuberculous empyemas including closed and communicating ones are extremely serious. The pleura may communicate with the exterior through a bronchial fistula or through an open chest wound or tuberculous sinus. A roentgenogram of an open empyema which demon-

Fig. 4.—X-ray of an endopleuronal of the pleura. Large tumor masses fill out almost the entire left pleural cavity.

strates an entirely collapsed and retracted lung is highly suggestive of tuberculosis. The lung in a non tuberculous empyema has no such tendency to remain entirely collapsed. The patient is often profoundly toxic and soon succumbs to fever, sepsis, and mild disease or distant tuberculous foci. The valve flap has been useful in obliterating the pleural space even in secondarily infected tuberculous empyema. After the pus has been drained and acute symptoms have subsided a more or less extensive thoracoplasty may be indicated if any of the empyema cavity remains to be obliterated.

Tuberculous empyemas communicating with a bronchial fistula must be drained

through the chest wall for constant cough and profuse expectoration soon exhaust the patient. (See the section on Surgery of Pulmonary Tuberculosis.)

Actinomycosis of the Pleura—Actinomycosis of the pleura causes huge hard deposits with periostitis and erosion of the ribs and vertebrae. The periostitis and erosion are typical of actinomycosis and occur in no other form of empyema. Large brawny infiltrates involving the whole thickness of the chest wall and multiple sinuses surrounded by easily bleeding granulations are characteristic of this disease. The sulfonamides and especially penicillin have led to striking results in the treatment of pleural actinomycosis which prior to their introduction was almost always fatal.

NEOPLASMS OF THE PLEURA

Pleural neoplasms are primary or metastatic the latter being more frequent. They may reach the pleura by continuity or via the lymph stream as in the carcinomatous pleurisy of cancer of the breast in which the pleura is studded with miliary cancerous nodules they may take the form of tertiary nodules in which a distant tumor causes pulmonary metastases which in turn reach the surface of the lung and spread into the pleural cavity. The cancerous pleura exudes a fluid which may be serous or more often blood tinged. If the primary tumor remains undiscovered the true nature of the pleurisy may be not easy to determine. A bloody fluid will awaken suspicion even the unstained centrifugate may contain microscopically recognizable clumps of tumor cells. Stained sections of the embedded sediment are more likely to lead to a correct diagnosis. Mottled erosion and involvement of the ribs visible in a roentgenogram are equally pathognomonic while actinomycosis may cause similar erosion it rarely causes a massive serous exudate. The disease is hopeless even cancer of the breast which is amenable to radiotherapy is refractory once it has settled in the pleura.

Hodgkin's Disease—Hodgkin's disease of the pleura manifests itself in a variety of forms miliary nodules, larger nodules and large tumor masses, diffuse pleural thickening, and a chronic sclerosing form have been described. The disease may cause the exuda-

tion of large amounts of a more or less turbid at times an almost purulent exudate and at times a chyllothorax. It may extend to the pleura from the mediastinal cervical axillary or intercostal lymph nodes or from a lymphoblastomatosis of the lung. Diagnosis will rest on the presence of Hodgkin's disease elsewhere and the identification of typical giant cells in the exudate. Bits of tissue may be removed with a large aspirating needle or by exploratory thoriotomy. Small doses of x-ray may give prolonged relief. Sunbaths, arsenicals, codliver oil and rest in bed are also beneficial when used together with the x-ray.

Benign and Malignant Primary Neoplasms—Of the numerous varieties of benign and malignant primary neoplasms which occur in the pleura two have clinical importance—the endotheliomas or mesotheliomas and the sarcomas. The exact histologic nature of the endotheliomas or mesotheliomas has been the subject of endless discussion. They form wide diffuse masses projecting into the pleural cavity at times as condylomatous villi and at times as solid lumps. They may make massive exudates the more fluid they form the flatter they seem to be, they rarely invade the lung but involve visceral and costal pleura alike. They involve the regional lymph nodes regularly and in three fourths of all cases they involve both sides of the chest. The right side is affected somewhat more often than the left.

All forms of sarcomas occur fibrosarcomas and lymphosarcomas chiefly they more often form large nodular masses than do the endotheliomas which are flatter they involve the left side twice as often as the right.

The endotheliomas when first seen often have attained a size and an extent that preclude operative attempts at removal although occasionally exploratory thoriotomy may be justified. Sarcomas tend to remain somewhat more localized and in instances of successful resection of these growths have been recorded.

POSTOPERATIVE ATELECTASIS, PULMONARY ABSCESS, GANGRENE AND BRONCHIECTASIS

POSTOPERATIVE ATELECTASIS

(*Marine Collapse of the Lung Drowned Lung*)

Definition—Atelectasis is a condition of complete uselessness of a lobe or a lung (massive collapse) or of a group of lobules (lobular or patchy atelectasis). Atelectasis is the most frequent postoperative pulmonary complication; it is often mistaken for pneumonia.

Pathology—The involved portion of the lung is completely useless, solid and much smaller than normal. The bronchus and its divisions that lead to the involved area are usually occluded by tenacious purulent mucus. The decrease in the size of the lung is compensated for by traction displacement of the surrounding structures: the heart or the heart and trachea may be entirely in the diseased side of the chest; the hemidiaphragm is elevated and the ribs are depressed. The contralateral lung and the unaffected portion of the diseased lung are overdistended.

Van Allen and Jung have shown that occlusion of a branch of a bronchus within a normal lobe does not result in atelectasis because interalveolar pores maintain an interlobular or collateral circulation of air. If however the alveolar walls should be diseased and the pores sealed the collateral circulation of air may be prevented; atelectasis of a part of the lobe would then occur.

Etiology—Complete occlusion of a lobar bronchus prevents air from entering the part of the lung supplied by that bronchus and the air that is already in the lung becomes absorbed by the blood within an hour or so. As the air is absorbed the walls of the alveoli and smaller bronchi are drawn together. The mediastinum, diaphragm and ribs follow the shrinking lung.

flex inhibition of the inspiratory muscles muscular weakness tight strapping of the upper abdomen and lower thorax abdominal distention or too large doses of opiates. Possible causes of increased production of tenacious bronchial secretions are pre-existing bronchitis allergy and an irritating anesthetic agent (though atelectasis often occurs after local or spinal anesthesia).

Fig. 478.—a Two days after a lateral neonatal herniorrhaphy under combined avertin and nitrous oxide anesthesia. The shadows in the left lung suggest early patchy atelectasis, and the heart is slightly displaced to the left. Dyspnea, a temperature of 103.8° F., 17,000 white blood cells, mucopurulent temporarily reddish sputum and abdominal distention were noted. The day before this roentgenogram was made there was much mucus in the trachea (and presumably in the bronchi) which the patient could not expectorate. b Four days later. Massive collapse of the entire left lung; the heart is greatly displaced to the left (the left border is indicated by an inked line); the diaphragm cannot be clearly seen. Periodic dyspnea but less fever and fewer leukocytes were noted. Treatment consisted of (1) inhalations of carbon dioxide in oxygen every three hours day and night, for the next two days and then less frequently; (2) flaxseed poultices and rectal tube for relief of abdominal distention; (3) intravenous fluids. c Four days later. Complete expansion of the collapsed lung and return of the heart to a normal position. There are no symptoms.

Occlusion of a bronchus by secretions is due to aspiration of oral secretions and retention of bronchial secretions owing to inadequate pulmonary aeration and ventilation and especially to ineffective coughing and expectoration. Decrease of respiratory excursions after operation especially an operation on the upper abdomen is chiefly due to pain, a fixed position of the body, re-

Symptoms and Physical Findings—The prompt recognition of the prodromal signs of atelectasis and complicating postoperative pneumonia is necessary for effective preventive treatment. These signs are frequent moist cough that continues to be moist even though some secretions have been expectorated, persisting rales, wheezes and diminished breath sounds by auscultation.

tion over the pulmonary base or bases elicited best during forced deep breathing or coughing perhaps slight dullness to percussion shallow rapid respiration rapid pulse and slight cyanosis. With the development of atelectasis the temperature and the pulse and respiratory rates mount cyanosis increases and in severe cases the patient may become comatose the wet cough is likely to be frequent and although some sputum may be raised the physical signs show that many secretions remain in the lung dullness of the affected lobes increases the breath sounds diminish and traction displacement of the mediastinum and diaphragm occurs.

If the secretions plugging the bronchi are evacuated within a few hours the lung may immediately become aerated (Fig 4-8 c) and all abnormal signs and symptoms except temporary expectoration disappear. If however bronchial obstruction is not relieved promptly and the bronchi are not kept patent by the efficient evacuation of all secretions infection is likely to develop in the obstructed segments of the lung producing a bronchial pneumonia which may prove fatal.

Diagnosis.—Moist ineffectual cough basal rales wheezes diminished breath sound and dullness with increasing fever and cyanosis are virtually diagnostic of developing atelectasis. A diagnosis of atelectasis is confirmed by traction displacement of the mediastinum and diaphragm which helps to distinguish atelectasis from pneumonia pleural effusion acute dilatation of the heart, coronary thrombosis pulmonary embolism and diaphragmatic hernia.

Prognosis.—Atelectasis of a lobe or even an entire lung is in itself not fatal although the anoxemia and increased cardiac labor that it produces may contribute to a fatal outcome of the disease for which the operation was performed. The possible complications of an atelectasis that is not promptly relieved viz pneumonia pulmonary abscess bronchiectasis and emphysema are serious and may be fatal. Recognition and treatment of the pre atelectasis stage of the condition are likely to prevent the development of a grave postoperative pneumonia. Early diagnosis of atelectasis and immediate adequate treatment bring about a cure without complications in a great majority of cases.

Treatment.—The following measures are highly effective in preventing postoperative atelectasis and pneumonia deep breathing coughing and if possible expectorating shortly before operation no atropine before or after operation not enough morphine before or after operation to obtund the cough reflex no anesthetic agent (e g avertin) that prolongs sleep after operation a 15 degree Trendelenburg position of the operation table when feasible gentle operating no tight strapping of the operative wound postoperative change of position every two hours so that each side is occasionally uppermost (the side having the more secretions and rales should be kept uppermost the longer time) voluntary (or induced by inhalation of from 10 to 15 per cent carbon dioxide in oxygen) deep breathing coughing and expectorating every three or four hours while a painful incision is manually supported by a physician or nurse Coughing and expectoration are favored by the Fowler position in some cases and by the Trendelenburg position in others. Secretions that cannot be expectorated should be promptly and if necessary repeatedly removed from the trachea and bronchi by Haight's method of intrabronchial catheter aspiration. Secretions too tenacious or abundant for removal by catheter should be removed bronchoscopically.

If neglect of these preventive measures results in atelectasis this should be treated by an intensive application of the same measures. The use of oxygen by intranasal catheter or by tent is advisable until the atelectasis has disappeared and until the patient is able to expectorate with proper efficiency.

NON TUBERCULOUS PULMONARY ABSCESS AND GANGRENE

Definition—A non tuberculous pulmonary abscess is a suppurating liquefying infection of the pulmonary parenchyma. Gangrene is the non purulent death *en masse* of pulmonary tissue. Since these two conditions are often associated and are treated in the same way they will be considered together here under the inclusive term of abscess.

Fig. 479.—The lung lobe opened vertically to show gross suppurative pulmonary infiltration and the necrotic irregular anterior wall of an abscess in the subacute phase. The right end of the probe passes through a perforation in the cortex and visceral pleura. The lobe has been sealed by fresh adhesions. The inserted photograph shows another section of the same abscess and a daughter abscess which communicates through a narrow channel that is opened by the probe. The probe points toward one of several open bronchi.

Pathology—An area of suppurative infiltration in the bronchioles or alveoli becomes transformed by necrosis and liquefaction into a pus containing cavity. The wall of the cavity may be thin or thick or composed of an extensive area of pneumonic infiltration. Early or late the pus within the cavity ruptures into a bronchus or occasionally into the pleural cavity causing an

empyema with or without a persisting bronchopleural fistula. Inflammatory pleural adhesions however usually prevent perforation into the pleural cavity (Fig. 479). After rupture into a bronchus the cavity may become filled with air or remain filled with grumous secretions or it may be filled with air and secretions (Fig. 480). The lumen of the bronchus leading from the abscess is often too narrow for adequate drainage of the secretions; the bronchial mucous membrane may be swollen and heaped with granulation tissue or the bronchial lumen may be occluded by a foreign body, a tumor, cicatricial contraction or extrabronchial pressure. Because of poor drainage by bronchus the abscess continues to be filled by secretions or filled partly by secretions and partly by air (Fig. 480).

Abscesses may occur in any lobe usually near the periphery and only rarely in the central or hilar zones. In a great majority of cases the abscess is within 1.5 cm. of the costal pleura and in a minority the abscess is in the cortex of the lung deep in one of the interlobar fissures or next to the mediastinum or diaphragm. An abscess may be single or multiple. When multiple they usually lie close together and may communicate through narrow channels (Fig. 479). Bands of tissue which are composed of bronchi or patent or thrombosed blood vessels may span an abscess or form ridges on its wall.

Etiology—Abscesses tend to occur in debilitated persons with pyorrhea alveolaris. The following sequence of events probably represents the etiological factors in the majority of cases: (1) the aspiration of infectious secretions from the gums, tonsils or sinuses into the lung during operation (especially on the teeth, tonsils or sinuses) or during sleep; also aspiration of food vomitus, water or other foreign bodies during submersion; (2) stasis of the aspirated secretions because of diminished respiratory movements and inefficient coughing chiefly due to prolonged deep anesthesia; postoperative pain or too large doses of morphine; (3) sufficiently long contact of the infectious secretions with the pulmonary tissue to establish an infectious process.

Other causes of abscess are suppuration and liquefaction within an area of delayed

resolution of pneumonia or within a pulmonary neoplasm or cyst; an embolus from an operative wound; pyemia; trauma of the lung with secondary infection; extension of infection from bronchiectases, and mycotic lesions. Streptococci and other pyogenic organisms are usually the causative agents. Spirochetes and other putrefactive organisms are frequent secondary invaders. The putrefactive organisms are usually the primary agents in pulmonary gangrene and in the so-called putrid abscess.

Symptoms.—The symptoms of onset may appear suddenly or insidiously and in-

Costal and diaphragmatic movements are restricted on the affected side. If the lesion is not too small, fremitus is usually increased and the percussion note impaired. In most cases the auditory signs are those of a small patch of pneumonic consolidation with râles, though the breath sounds may be diminished or absent; cavernous signs are sometimes demonstrable, a pleural friction rub may be heard. A localized area of intercostal or periosteal tenderness indicates the place where the abscess is most superficial.

Roentgenologically, there is usually an irregular area of density in which a small air

Fig. 480.—a, Abscess of the lower lobe filled with air and pus seven weeks after partial gastrectomy, arrows indicate the limits of the abscess as determined the next day at open operation. b, Several days after drainage of the abscess. The clear area lateral to the costal stump is due to an operative defect in the thoracic wall. The arrow indicates the position of a second abscess containing pus but no air. The existence of a second abscess was suspected when abundance of sputum persisted after drainage of the first abscess. The second abscess was drained nine days after the first operation and was found to be 8 by 4 cm. in size. c, End result nine months after drainage: no cough or expectoration remains, and the wound is healed. * Today only a short piece of one rib would be resected for the drainage of each abscess.

clude varying degrees of malaise, fever, cough, expectoration and, perhaps, pleural pain, chills, dyspnea and cyanosis. At first there may be no sputum; it may appear in small amounts and gradually increase, or, following the sudden rupture of a large abscess into a bronchus, a tremendous amount of sputum may be evacuated within a few minutes (vomica). The sputum is purulent; it may be odorless, but usually it has a fetid or sweetish odor. The first expectorated material may be pure blood, large or small hemoptyses or blood-streaking of the sputum may recur throughout the illness.

pocket can often be seen; this air is within the abscess cavity, the greater part of which is filled with heavy secretions. In some cases a considerable amount of air is present in the cavity (Fig. 480, a), while in others the cavity is completely filled with secretions which give a roentgenologic shadow that is homogeneous with the abscess wall (Fig. 480, b). Potter-Bucky roentgenograms may be necessary to demonstrate air-containing cavities within a densely infiltrated lung. Bronchograms should rarely be made, because lipiodol may induce a dangerous pneu-

monitis in cases of acute abscess and be cause the lipiodol is more likely to indicate merely a filling defect in the region of the pulmonary infiltration than to enter the abscess

In cases in which the suppurative infiltration and excavation are progressive the patient becomes increasingly toxic and dies from the effects of the overwhelming infection or from brain abscess rupture of the lung and fulminating empyema large hemoptyses or suppurative pneumonitis In chronic cases with less severe infection pulmonary fibrosis extension of the infection bronchiectasis clubbed fingers and toe nephritis and amyloid disease often grad

and bronchogenic carcinoma The difficulty of diagnosis is increased by the fact that each of these conditions may be complicated by pulmonary abscess The differential diagnosis can however almost always be made by the careful weighing of the findings in their relation to the characteristic features of the various diseases Diagnostic aspiration of an abscess through the skin should never be undertaken because of the danger of infecting the pleural cavity and tissues of the thoracic wall via the needle track

Prognosis—Possibly as many as 30 or 40 per cent of patients with uncomplicated abscesses recover spontaneously without

Fig 481—*a* First sized abscess with many open bronchi in the lower lobe approximately one year after surgical drainage the sputum and purulent wound discharge are now absent *b* Eighteen days after filling of the abscess cavity and occlusion of the open bronchi with a large pedicled muscle graft There is no sputum and closure of the bronchi and of the incision is complete

ually develop Remissions and exacerbations of symptoms may be expected

Diagnosis—A history of an operation or aspiration of a foreign body followed by an acute illness with the expectoration of abundant foul purulent sputum which has been repeatedly found to be free of tubercle bacilli the absence of traction displacement of the diaphragm and heart and the presence of the physical and roentgenologic signs that have already been considered are findings that are virtually diagnostic of abscess

Diagnostically abscess may be confused with tuberculosis bronchiectasis empyema with bronchopleural fistula a subphrenic abscess that has ruptured into a bronchus

other treatment than bed rest If such recovery does not occur within two months after the onset of symptoms it is unlikely to occur Usually only the patients with severe complicated or chronic cases reach the surgeon and in approximately 5 or 10 per cent of the acute cases and 20 per cent of the chronic cases death occurs The prognosis depends chiefly on the adequacy of bronchial drainage the virulence of the infection the patient's general condition and specific resistance and the extent duration and complications of the lesions at the time that effective treatment is begun The prognosis depends largely upon carrying out surgical drainage very early in the disease as has

been amply demonstrated by Neuhof and Touroff.

Treatment.—Prophylactic treatment is essentially the same as that described in the section on treatment of atelectasis (see previous section). A patient with an acute abscess should be strictly confined to bed under a sanatorium regimen. He should not sleep on the undiseased side, because of danger of gravitation of infectious secretions to the undiseased lung while the protective cough reflex is relatively inactive. Postural drainage should be effected every two hours while the patient is awake. In occasional cases in which bronchial drainage is free, the hemidiaphragm should be temporarily paralyzed in order to rest and relax the affected area. Bronchoscopy should be tried at least once and continued at three day or five day intervals only if great improvement occurs; the aspiration of secretions, the shrinking of the swollen mucous membrane and the possible detection and removal of a foreign body promote adequate bronchial drainage which may initiate healing. Pneumothorax is dangerous treatment for a non-tuberculous abscess, and thoracoplasty is only rarely indicated. Vaccines are probably of no value. When spirochetes are present in the sputum, a course of salvarsan or neosalvarsan may be given intravenously. Blood transfusions are useful for severe anemia.

Until a few years ago there was an almost universally accepted dictum that no acute pulmonary abscess should be surgically drained within eight or ten weeks of its onset. The clinical demonstration by Neuhof and Touroff that this practice leads to a high mortality rate and great morbidity has caused a rapidly increasing acceptance of their advice to drain abscesses as soon as a diagnosis has been made and a brief trial of other measures has failed to indicate rapid progress toward a cure. These surgeons stress the importance of accurate localization and one stage drainage after the resection of a short piece of only one rib where the abscess is most superficial and where the pleurae are adherent. Cautery drainage must include any secondary abscesses that may be present and may need to be so extensive as to constitute partial lobectomy. After complete disappearance of sputum and of purulent discharge from the wound

following drainage, bronchial fistulas that do not close spontaneously should be closed with applications of a 35 per cent solution of silver nitrate or with a pedicled muscle or

Fig 482.—Implantation of the breast to fill a tremendous intrathoracic defect and to occlude the large open bronchi that followed destruction of the entire upper and most of the middle lobes by multiple progressive abscesses and many cauterization drainage operations. There is no sputum and closure of the bronchi and of the incision is complete.

skin graft (Figs 481 and 482) or with Neuhof's free fat graft. Occasionally, total lobectomy should be performed in resistant cases of huge abscess or multiple abscesses.

BRONCHIECTASIS

Definition.—Bronchiectasis is a chronic condition of dilatation of the bronchi, which are usually infected and secrete abundant pus.

Pathology.—The lesions are bilateral in approximately half of all cases. They may be confined to any one lobe (especially the left lower), but more frequently they involve the left lower and the lower part of the left upper lobes, or the right lower and middle lobes.

Peripheral or bronchiolar bronchiectasis

involves the small bronchi and bronchioles whereas the common central bronchiectasis involves the larger bronchi. The dilations are saccular or cylindrical. The pulmonary parenchyma surrounding central bronchiectases may be almost entirely normal, the covering pleurae glistening and without adhesions and the lung normal to palpation except perhaps for some hard lumps. Frequently, however, the parenchyma is the seat of fibroid pneumonitis, the lobe is shrunken, dark and indurated and its pleurae are adherent. The diseased parenchyma may contain abscesses. An empyema with or without a bronchopleural fistula may be present.

Obiectasis are aspiration of nasal sinusitis secretions, a retained bronchial foreign body, intrabronchial neoplasm, tuberculous or non-tuberculous granulation tissue or fibrous stricture of a bronchus and extra-bronchial pressure by enlarged lymph nodes or other masses. Pulmonary abscess and tuberculous (without bronchial stricture) are infrequent precursors of bronchiectasis although they are occasionally complicated by patches of bronchiectases. Some cases of bronchiectasis are congenital in origin. Allergy coexists with bronchiectasis in many cases and a few observers believe that allergy is a frequent cause of bronchiectasis.

Symptoms—The most prominent symp-

Fig 483—Bronchograms of the three lobes of the right lung showing a normal upper lobe and bronchiectasis of the middle and lower lobes. As the shadows of the middle and lower lobes are superimposed on the postero-anterior projection roentgenogram, only the lateral projection roentgenogram clearly shows that both the lower (posterior) and the middle (anterior) lobes are involved.

Etiology—Bronchial pneumonia (often complicating measles or pertussis in childhood or influenza) is the commonest precursor of bronchiectasis. The probable explanation is that stagnation of secretions in the bronchi, partly produced by poor pulmonary ventilation, causes patchy or lobar atelectasis and the resulting highly negative intrathoracic pressure, not being absorbed by the inelastic atelectatic lung, is transmitted to the bronchi which dilate. Concomitant infection in the bronchial walls weakens them and the dilatation remains even after disappearance of the atelectasis. Conditions less frequently leading to bron-

tom is persisting abundant expectoration. The sputum may be either foul or non-odorous, blood streaked, sputum or recurring large hemoptyses are not uncommon. There are no bronchial secretions in bronchiectasis sicca. Fever is rare when there is no bronchial obstruction or complicating suppurative pneumonitis. Clubbed fingers and toes and nasal sinus infection are frequently present.

The physical signs of even extensive central bronchiectasis (without accompanying pneumonitis) are often within normal limits though there may be a slight increase in fremitus and a few rales. When pneumonitis

is present the signs are those of varying degrees of pneumonic consolidation with or without signs of cavitation.

The symptoms and signs that have been mentioned are common to bronchiectasis, abscess, certain empyemas with broncho-pleural fistula and some cases of tuberculosis. Bronchograms offer the most certain means of diagnosing bronchiectasis (Fig 483). The opaque oil which fills the bronchi or coats their walls (unless retained secretions or organic bronchial stricture prevents the passage of the oil) clearly demon-

Diagnosis—Although the diagnosis can often be tentatively made on the basis of the history and symptoms, a definite diagnosis and determination of the extent of the disease depend on bronchograms. Before these are made bronchoscopy should be used to detect a possible foreign body or neoplasm. The separation of the sputum into three layers after standing is of little diagnostic value.

Prognosis—Bronchiectasis which is essentially a chronic disease is so variable in its behavior that it is impossible to foretell

Fig. 484—Twenty two days after removal of the left lower and lingular lobes for bronchiectasis. No deformity or dysfunction of the shoulder girdle resulted.

strates the bronchiectases even in the left lower lobe behind the heart. Roentgenograms without iodized oil show no abnormalities or perhaps only small ring shadows unless there is associated pneumonitis.

Stewart Pritchard and Ross found that their 60 bronchiectatic patients had a total of 240 complications. Common complications are disease of the nasal sinuses, recurring attacks of pneumonia or acute extension of the lesions of suppurative pneumonitis, hemoptyses, nephritis, amyloid disease, myocardial degeneration and brain abscess.

accurately either the expectancy of life or the course and severity of future symptoms. The chance is great, however, that the patient will suffer serious illness or will die within five years of the onset of the disease. Except possibly in early cases in children the dilated bronchi never return to their normal caliber. Appropriate treatment may greatly reduce infection and enable the patient to live indefinitely with few disturbing symptoms. In some cases no treatment except actual removal of the diseased tissue by lobectomy is able to check the infection.

and to prevent complications. Death from bronchiectasis is usually due to some complication the most common being pneumonitis the effects of prolonged toxicity and brain abscess. A few patients commit suicide because of the stench and the great amount of sputum. Even massive pulmonary hemorrhage is in itself rarely the cause of death.

Treatment. — Prophylactic treatment should be directed toward the immediate removal of an intrabronchial foreign body eradication of infection in the gums and nasal sinuses active treatment of delayed resolution of pneumonia by prolonged strict bed rest a trial of one of the sulfonamides and of penicillin postural drainage every two hours possibly temporary or permanent paralysis of the phrenic nerve one or more courses of neosalvarsan if spirochetes are present in the sputum repeated bronchoscopic aspiration of secretions shrinkage of swollen mucous membrane and dilation of any bronchial stricture.

The measures that have just been named should be used for an established case of bronchiectasis though it is doubtful if neosalvarsan is of value in a chronic case. Postural drainage is indispensable and if the bronchi are kept relatively free of stagnant secretions infection in their walls tends to subside the amount of sputum the odor and hemoptyses tend to lessen and the patient's weight and general condition improve. Although in a majority of cases phrenic paralysis proves to be of no benefit it sometimes stops hemoptyses and greatly reduces the amount of sputum if it is found to be effective a temporary paralysis may be made permanent. Blood transfusions should be used for severe anemia that does not respond to the administration of iron. Vaccines are of no value. Residence in a warm dry climate may prevent recurring attacks of pneumonitis improve the sinus infection and lessen the amount of bronchial secretion.

Pneumothorax probably should not be used for bronchiectasis though occasionally when pleural adhesions do not prevent an adequate pulmonary collapse great improvement may attend this procedure remission is likely to occur after abridgment of the pneumothorax. Thoracoplasty is a danger-

ous operation in bronchiectasis and only exceptionally produces any lasting benefit. Thoracoplasty may however be indicated in certain cases of the rare peripheral type of bronchiectasis and in cases in which there is great traction displacement of the mediastinum because of pulmonary and perhaps pleural fibrosis. Surgical drainage of the bronchiectases should not be used though occasionally a large complicating abscess demands drainage. An area of bronchiectasis restricted to a small portion of one lobe may be destroyed by a staged cauterization operation.

For the patient whose lesions resist the various measures that have been discussed and whose disease is severe because of toxicity abundant foul sputum recurring at attacks of pneumonia or large hemoptyses lobectomy should be considered or even pneumonectomy if the disease occupies an entire lung. The patient should be in reasonably good general condition preferably less than forty-five years of age and the lesions should be confined to one lung or at least minimal in extent in the less diseased lung. The surgical risk of bilateral lobectomy for bilateral bronchiectasis is relatively great. The death rate from unilateral lobectomy has been reduced in several clinics to less than 5 per cent which is considerably less than the risk to life of the disease itself. A successful operation causes complete disappearance of all symptoms of bronchiectasis (Fig. 481).

TUMORS OF THE LUNG AND BRONCHI

PRIMARY CARCINOMA

Carefully evaluated statistics appear to indicate that the incidence of primary carcinoma of the lung has definitely increased

Various causes have been invoked, among them the inhalation of tar dust from roads the influenza epidemic of 1918 and tobacco smoking. A high incidence of primary carcinoma of the lung has been observed for centuries among the Schneeberg miners in Saxony ("Bergrkrankheit"), and the phenomenon has been attributed to the radioactivity of the ore. In general, however, the origin of pulmonary carcinoma is as obscure as that of other neoplastic disease. There is no evidence to show that pulmonary tuberculosis plays an important role as a predisposing factor.

Classifications of primary carcinoma of the lung have been based on the appearance of the disease at gross, the roentgen ray shadows and the symptomatology. These descriptions are usually without special significance based as they are on advanced stages of the disease. As with other tumors the classification on the basis of cell type will prove the most informative to the surgeon.

It is not surprising to find confusion regarding the histogenesis of primary epithelial tumors of the lung when a divergence of opinion exists in regard to the histology of the normal lung. The point at issue is whether or not the normal alveolus possesses a lining membrane of epithelial cells. Those writers who deny the existence of such a structure must perforce deny the alveolar origin of epithelial tumors and ascribe a bronchogenic origin, i. e. from the epithelial elements of the bronchial mucous membrane in all primary carcinomas of the lung. The evidence at hand at the moment is far from conclusive and the concept of an alveolar epithelial membrane cannot be discarded or its possible role in the histogenesis of primary epithelial neoplasms ignored. On the other hand an alveolar origin cannot be established with certainty after a tumor has developed.

Bronchial mucous membrane may exhibit a marked degree of metaplasia in chronic inflammatory lesions entirely unassociated with neoplasm. The lining membrane of bronchiectatic cavities is frequently of the squamous cell type. Epithelioid carcinomas of the squamous cell type with or without epithelial pearl formation or prickly cell differentiation may be derived from the elements of the bronchial epithelium even though this structure is normally cuboidal or cylindrical in form. A single tumor may show varying degrees of metaplasia within its structure forming a polymorphic or mixed type of growth.

A simple classification of primary carcinoma of the lung based on histologic characteristics is as follows:

1 *Squamous cell epitheliomas* of the multiphase type with varying degrees of cell differentiation. Huguenin has also described a "paramultiphase" type with larger polyhedral cells.

2 *Adenocarcinoma* cylindrical or cuboidal cells appearing to form gland like structures. At times the acinar structure is so differentiated as to produce a colloid type which is well demonstrated by the mucicarmine staining reaction.

3 *Small cell type* ("oat cell") a cell rich carcinoma composed of small fusiform cells with very little stroma. These tumors have frequently been termed lymphosarcomas because the cells resemble lymphocytes when sectioned transversely. The tumor is partic-

Fig 483—Metastases and routes of direct extension of three typical primary carcinomas of the lung. (See text.)

ularly apt to invade the mediastinum and lung in a diffuse infiltration. The histogenesis is peculiarly obscure and controversial.

4 *Undifferentiated types*

Metastases—The conception that primary carcinoma of the lung is highly malignant and peculiarly prone to widespread extension and metastases was based on autopsy findings in advanced cases. An earlier recognition of the disease and its treatment by surgical measures has already altered this concept. Primary carcinoma of the lung spreads to distant sites by both lymphatic and hematogenous routes (Fig 485). The

bronchial and mediastinal lymph nodes may be invaded early. Blood stream metastases appear to find particularly favorable soil in the brain, the liver, the adrenals and the kidneys. Metastases of carcinoma of the lung may also be aerogenous—a method of extension peculiar to this tumor. Fragments of tumor tissue not infrequently appear in the sputum (Fig 485) and when such a fragment is conveyed to a distant part of the lung by cough it may establish a secondary focus of the disease (Fig 485 A).

As is the case with other tumors carcinoma of the lung also progresses and kills by direct extension. Common types of extension are illustrated in figure 485. Direct

Fig 486—Pathogenesis of symptoms and signs in primary carcinoma of the lung (See text)

extension to the mediastinum is frequent and invasion of the pericardium, the great vessels or the heart muscle itself may occur. Invasion of the diaphragm may be followed by extension through its peritoneal surface and a plaque of carcinoma may be deposited on the dome of the liver.

The degree of malignancy as indicated by the rapidity of metastases and local extension has not been adequately correlated with the histologic type of individual tumors. In general the oat cell and undifferentiated types are rapidly invasive tumors poorly suited to surgical extirpation. Tumors of the squamous cell type may be expected to yield the most favorable results after surgical treatment. Careful clinical records and particularly an increased experi-

ence with surgical measures will increase our knowledge in this regard.

Symptomatology—Primary carcinoma of the lung is as protean in its symptomatology as it is polymorphic in its histology. Figure 486 portrays the pathogenesis of the common manifestations of the disease. It is to be emphasized that a single growth usually produces symptoms or signs by several of these mechanisms appearing simultaneously or in sequence so that the diagram is not to be interpreted as a classification of disease types.

The following headings refer to the numbers of the tumors in figure 486. Cough may be a symptom common to all of the lesions pictured and is usually the earliest and most constant manifestation of the disease. The cough may develop suddenly but more frequently its onset is coincident with an acute respiratory infection which simply means that a partially obstructed area of lung has become infected. A cough that hangs on in a patient who has previously been well deserves careful diagnostic study. Clubbing of the fingers or more extensive pulmonary osteoarthropathy may be an early manifestation of the disease.

1. A tumor in close proximity to the visceral pleura may produce a pleural effusion which may or may not be preceded by dry pleurisy. The effusion may be serous but is characteristically bloody. When actual invasion of the pleura exists (Fig 486 type 3) tumor cells may be found in the sediment of the fluid.

2. Tumors in the parenchyma of the lung may be silent for a long period and are discovered only accidentally by a routine x-ray examination or by the development of a distant metastasis.

3. When a tumor completely occludes a sizable bronchus the corresponding area of the lung becomes airless and drowned by the imprisoned bronchial secretions. The bronchi become dilated and depending on the type and virulence of the bacterial flora pneumonia or abscess formation results. The physical signs of complete bronchial obstruction must be carefully analyzed as they closely simulate those of a localized pleural effusion. The breath sounds remain vesicular but are faint or totally absent in contrast to the bronchial breath sounds.

characteristically heard when fluid is present there is no egophony. Resonance is impaired and tactile fremitus diminished with atelectasis but usually not to a degree simulating the flaccid and absent tactile fremitus of fluid. Signs of a blocked bronchus may be recognized even in the presence of fluid if the breath sounds are faint but vesicular in quality or totally absent. Signs of a closed bronchus are usually an indication for bronchoscopic examination.

4 A tumor of the extreme apical region may manifest itself by invasion of the adjacent structures. The superior sulcus syndrome described by Pancoast is (a) *paralysis of the sympathetic trunk resulting in a Horner's syndrome* (b) *invasion of the first dorsal root of the brachial plexus giving pain referred to the arm and partial paralysis of the ulnar and median nerves* (c) *erosion of the ribs demonstrable usually by x-ray examination*. The tumor itself may be visualized with difficulty in the x-ray film in early cases.

5 A primary tumor or metastatic deposit may cause paralysis of the recurrent laryngeal or phrenic nerves on the involved side by direct invasion of the mediastinum.

6 A tumor that incompletely obstructs a large bronchus frequently causes a wheeze noted by the patient and audible as sibilant rales to the examiner. The wheeze may be localized by the patient or the examiner as unilateral thus differentiating it from bronchial asthma. Such a partial obstruction may also cause obstructive emphysema or trapping of the air on expiration in the corresponding area of the lung, a phenomenon demonstrable by x-ray films taken in full inspiration and expiration respectively. Recurring attacks of pneumonitis diagnosed as bronchitis or bronchopneumonia punctuate the case history.

7 Ulceration of the bronchial mucous membrane gives rise to the blood streaked sputum or recurrent hemorrhages so characteristic of carcinoma of the lung. This symptom frequently leads to the erroneous diagnosis of pulmonary tuberculosis—a diagnosis that should always be questioned in the absence of a positive sputum.

8 Many tumors undergo central necrosis with cavitation and the establishment of a bronchial fistula. The sputum may be foul

and obnoxious and often blood streaked. The differentiation between this type of lung abscess and the type uncomplicated by malignant disease may become apparent only at an operation to establish drainage.

9 Irritation of the central portion of the diaphragmatic pleura by extension of a growth gives pain of typical phrenic nerve distribution as the first symptom.

10 Occasionally primary carcinomas of the left lung invade the esophagus producing obstruction or ulceration. The diagnosis may be established by esophagoscopy.

Diagnosis—The diagnosis usually depends on the recognition of a suggestive history and physical signs and is confirmed by roentgen ray examination. Although x-ray films may at times establish a definite diagnosis they frequently portray only the pleural effusion or the drowned lung that is produced by the primary tumor. Bronchoscopy may establish a positive diagnosis if a bit of the tumor can be removed for microscopic examination. Many tumors such as 1 2 3 4 5 6 and 9 in figure 486 may not be reached by the bronchoscope so negative evidence by no means excludes the diagnosis. In a large number of cases positive diagnosis by bronchoscopy may be expected in approximately 75 per cent.

Treatment—Unless definite evidence of metastasis or inoperable extension of the growth is at hand a patient with a primary carcinoma of the lung should be subjected to open thoracotomy to determine whether the growth can be resected. Treatment by radiation is palliative at best but may be elected as preferable to surgical treatment if the carcinoma is of the oat cell or undifferentiated type and if the likelihood of complete extirpation is minimal. The extent of the opacity in an x-ray film is not a true index of the size of the growth as the shadow may in part be due to the collapsed and consolidated parenchyma of the lung. An artificial pneumothorax at times is an aid in determining operability.

It has been repeatedly demonstrated that an entire lung may be removed with operative recovery of the patient and that single lobes may be removed with immediate palliation of distressing symptoms. Instances of a five or more year arrest of the disease following extirpation are rare but of increasing

frequency. The problem for the immediate future is that of all forms of malignant disease—earlier diagnosis to secure the proper treatment for the patient at a time when the disease is still localized.

The suffering in the terminal stages is often extreme. At times the course of illness is very slow and the patient's life is made miserable for months by severe pain, dyspnea, harassing cough and foul sputum. Uncontrollable hiccoughs, alarming hemorrhages, headache and loss of vision from cerebral metastases may be mentioned as typical of other distressing sequelae that combine to make the patient's existence intolerable.

METASTATIC TUMORS

Metastatic tumors in the lung are far more common than primary growths and are usually terminal events in a widespread dissemination of the disease. They rarely produce bronchial obstruction or hemoptysis, although at times secondary tumors possibly representing metastases to the bronchial walls closely simulate primary carcinoma. Resection of pulmonary metastases is an experimental undertaking but has been proved of life-saving importance in hypernephroma.

BRONCHIAL ADENOMAS

Circumscribed tumors of undetermined cellular origin are encountered as a cause of partial or complete obstruction of the larger bronchi. These tumors ultimately kill the patient by bronchial obstruction and infection. Hemoptysis is usually an early symptom and may be the only manifestation of the disease over a period of years. If the tumor is pedunculated it may be removed by the bronchoscopic but usually the broad base of the tumor and its extrabronchial extension make this impossible. Resection should then be undertaken. These tumors have in the past been mistaken for primary carcinoma of the lung even on microscopic examination of a fragment removed for biopsy. Segregation of this tumor is of extreme importance when dealing with statistics pertaining to primary carcinoma of the lung. Other benign tumors of the lung and bronchi are rare.

SURGERY OF PULMONARY TUBERCULOSIS

General Considerations.—Tuberculosis is a chronic systemic disease caused by the tubercle bacillus. It has a tendency to heal. General rest and expectant treatment are based on this fact. When pulmonary tuberculosis becomes clinically manifest it is expedient to consider the disease more serious than the symptoms indicate and to institute appropriate treatment promptly. The therapeutic result will be proportionate to the degree and duration of the rest attained.

Rest must be physical, physiologic and psychic. No less important it must be timely. It is much easier to prevent than it is to cure tissue destruction and complications.

The first rational step in the treatment of pulmonary tuberculosis was taken by Detweiler when he adopted Brehmer's idea of the sanatorium and added the principle of systemic rest to conserve vital energy. Rest is and will continue to be, the basis of phthisiotherapy. Additions to the armamentarium can be only supplementary.

James Carson in 1821 was the first to appreciate the favorable effect of pneumothorax and pleural effusion on the diseased lung. He recommended the induction of graded pneumothorax in the treatment of pulmonary tuberculosis to secure local rest of the lung through relaxation. He stated that retraction of cavities by surrounding structures is the greatest barrier to healing. If ever phthisis is to be cured it must be accompanied by mechanical means.

Some sixty years later Potain¹ made similar observations. In 1884 Forlanini, the apostle of artificial pneumothorax, firmly es-

tablished the importance of artificial pneumothorax in order to secure local or physiologic rest

Artificial or induced pneumothorax the second rational step in the treatment of pulmonary tuberculosis has become the most valuable addition to phthisiotherapy. It marks the transition from the passive or expectant regimen to that of active or aggressive collapse therapy.

The benefit of early local rest on the dominant lesions in the lung has been and still is too long deferred. An early pneumothorax is prophylactic; it is more efficient and no greater hazard than later pneumothorax. An efficient pneumothorax cannot always be induced or be continued over a sufficiently prolonged period of time—months or years—to insure success. Delay in the induction of a prophylactic pneumothorax permits conditions to develop within the pleural cavity and lung which will interfere with its later efficiency.

The third and most recent forward step in the treatment of pulmonary tuberculosis is the securing of mechanical relaxation and compression through surgical intervention. Every patient who presents indications for the more radical procedures for surgical collapse is a living example of failure. Failure of the physician to diagnose the case early to appreciate the gravity of the disease and to institute promptly and to continue rigidly the appropriate conservative measures, failure of the patient to cooperate or of the disease to respond to expectant treatment, failure to resort early to the less radical measures for collapse therapy.

Early diagnosis of tuberculosis is not in any way easy. The very severe forms may be confused with la grippe, influenza and pneumonia. The mild case may simulate a common cold, a recurring or chronic bronchitis. It must be borne in mind how almost universal tuberculous infection is and how commonly it can be activated. It is almost axiomatic that in all pulmonary diseases from the insidious through the very acute to the chronic forms tuberculosis should be considered a probability which should be verified by early and in doubtful cases repeated x-ray examination. If the physician is tuberculosis minded, he will more frequently and much earlier detect its presence at a

stage when the most can be accomplished by medical measures.

Each patient differs in his general and local reaction to infection. The dose and degree of virulence of the infection and the grade of susceptibility which fluctuate from time to time determine the course the clinical symptoms and the pathologic changes.

The response to therapy likewise varies. Each patient must be treated individually; no inflexible rule can be made to fit all cases. The pulmonary lesions are an accurate index of the trend of battle between the tubercle bacillus and the resistance of its host. The evolution of the local lesion must be as closely followed as is the general progress made by the patient in order to estimate his ability to overcome the disease.

Repeated examination of the chest and lungs checked by periodic x-ray study gives information more valuable than taking the temperature and the pulse.

Early diagnosis, early controlled general rest, early local rest secured by early pneumothorax, early interruption of phrenic nerve conduction and early surgical collapse mean early resolution. There is an optimum time for each form of therapy and a favorable opportunity lost renders general conditions more serious and local lesions intractable.

General rest and expectant treatment should be tried for a reasonable time, a period expressed in terms of weeks. There are many patients whose lesions cannot be controlled by general measures alone or who for economic, social or temperamental reasons cannot be favorably influenced by the usual conservative measures. Should favorable progress fail or cease, measures to secure the additional benefit of local rest exercised by collapse therapy are promptly indicated. "We must obtain promptly the minimum collapse of the lung that is conducive to healing all the tuberculous infiltration and cavitation." The earlier a focus not controlled by expectant treatment is attacked by collapse therapy, the more certain, rapid and favorable will be the effect and the fewer will be the complications. Destruction of tissue will be prevented and drastic operations avoided. This is as truly conservative in pulmonary tuberculosis as it is in cancer. Late operations are always of

greater magnitude and danger and the results are more uncertain than with early operations

Surgical treatment cannot eradicate tuberculosis especially in its pulmonary localization. It is not a substitute for but a supplement to accepted procedures when these after a reasonable trial have failed to establish a resistance balance against the disease.³

The patient who has not been cured by expectant treatment and who has not had favorable results from artificial pneumothorax or other comparatively minor collapse procedures is a candidate for the more radical forms of surgical collapse. Such a patient is usually in the advanced stages of the disease with vitality depleted, other organs compromised by prolonged toxemia or the tuberculous disease disseminated to other parts. He is psychically depressed when referred for operation as a court of last resort. This all too general tendency to recommend surgical intervention only as a last resort is not giving the patient the best advice; it places an unfair burden on the surgeon and it deters patients with earlier cases requiring operation from availing themselves of its benefits when the conditions are more propitious. Notwithstanding this attitude many persons who would have died have been restored to lives of usefulness. Many more could be more promptly restored if surgical intervention were invoked before the patients become standard risks.

The value of surgical compression therapy is no longer a matter of doubt. It is an incontrovertible fact demonstrated by successes wherever its limitations and possibilities are thoroughly understood.⁴

The purpose of collapse therapy is to prevent the development of restraining mechanical factors or to eliminate the impediments to relaxation and contraction when they have formed.

It is desirable in fact necessary to obtain early and complete closure of all forms of cavities as soon and as safely as possible.⁵

The aim of surgical collapse is to compress cavities and control the interposed lesions which are inimical to the orderly process of healing. The more selective the collapse the less will healthy lung tissue be

impured; the less embarrassed the respiratory function the more satisfactory the immediate effect and the better the final result. Ablation of a greater mass of lung tissue than is absolutely necessary should be avoided. Surgical collapse is irretrievable. A permanent burden is thrust on the remaining lung which is nearly always or may subsequently become involved to some degree. One can never foresee the demands that may be made on the remaining lung.

A surgeon should approach a case of pulmonary tuberculosis from a medical no less than from a surgical viewpoint. He should collaborate with the radiologist and the phthisiologist who must also become surgically minded. The future of the patient is much safer when he is under the care of men who understand both aspects of his disease.

Before deciding on operative intervention a careful and complete examination of the patient, review of his history and meticulous study of the evolution and the present status of the lesions in the lung, so graphically and chronologically recorded by a series of x-ray films are imperative. This information is of inestimable value in deciding what if any surgical treatment is indicated.

General rest lessens the physiologic activity of the lung. The activity of a locally relaxed or compressed lung area is in inverse ratio to the degree of relaxation or compression. With maximum compression the area is in the highest attainable degree of rest. Accumulated secretions in the lobules and bronchioles and exudate in the tissues are expressed and prevented from reaccumulating. Alveoli, smaller bronchi and cavities are made permanently smaller. Aeration is prevented. After the first or expression stage of compression the circulation of blood and lymph in the area is retarded. The absorption of toxins and bacteria is reduced by blocking the avenues of absorption. The blood and lymph stasis laden with toxins incites a progressive fibrosis and an increasing local resistance throughout the area. *Unimpeded fibrosis and only this can and will obliterate cavities and heal the pericavitary lesions.* When the overload has been removed the patient's general resistance is increased and other even distant foci may be benefited or healed. The curve of the clinical symptoms and local pathologic

changes follow each other closely but do not coincide

Man made factors and treatment only modify local and general conditions giving advantage to natural reparative processes

If completion of fibrosis and contraction is interrupted by inadequate or temporary compression the lesions may again become active. The partially compressed and fibrosed cavities may be pulled open or new cavities and foci may form adjacent to the old. Adequate prolonged compression facilitates permanent obliteration and is conducive to healing of cavities and pericavitary lesions. No operation can do more.

For a lasting cure it is obligatory for the patient to continue for months after operation a graded rest regimen. During the first postoperative month the opposite lung in becoming adjusted to the increase in its work undergoes hypertrophy. This may reach 50 per cent above normal.*

Increase in physiologic activity on the non operated side may reactivate any of its low grade or dormant foci.

Uneven postoperative stress of the contracting fibrosis on the larger bronchi may cause irregularities of their lumen. A low grade bronchiectasis is developed. This explains in part a persisting morning cough with small amounts of tenacious bacilli free sputum.

Pathologically, following invasion there are four stages of pulmonary tuberculosis: infiltration, destruction, excavation and resolution. These are present in mixed degree and their clinical symptoms therefore can not be sharply classified. Other factors notably allergy, which cannot be so clearly demonstrated have potent influences on the character and severity of the perifocal reaction and the general symptoms.

Cavitation.—Cavities with their pericavitary lung field present the chief obstacle to recovery and their obliteration is the major problem of collapse therapy.

To classify cases of pulmonary tuberculosis for collapse therapy a distinction may be made between those with and those without cavitation.

Cavitation a complication of pulmonary tuberculosis is generally considered a late manifestation. Cavities may and do form in the early weeks of disease.

The early cavity may be clinically silent. Unless careful and repeated x ray study is made cavities may escape detection until the characteristics of irremediable destruction or chronicity are established.

Cavities form when the balance between tissue destruction and tissue resistance is attained. The formative phase may be considered a conservative process. As long as a cavity remains it is a positive menace. Though a well drained clean cavity is compatible with years of life there is always danger of mixed infection, perifocal spread, intractable pleuritic adhesions, bronchogenic extension to other parts of the same or to the opposite lung and dissemination via the lymph or blood stream to other organs and tissues of the body. Hemorrhage, severe or repeated, spontaneous pneumothorax, serous or purulent effusion, broncho-pleural fistula or pyopneumothorax may develop.

Cavities are more serious in the exudative than in the fibrotic types of the disease when bronchial drainage is poor and in the younger than in the older patients.

The size, number and location of cavities, the character of their walls, the extent and nature of the reaction in the pericavitary lung field, the presence, character and number of pleuritic adhesions, the firmness or mobility of the mediastinum and the diaphragm, the conformation and rigidity of the chest wall, the efficiency of bronchial drainage and the amount and character of the sputum must be studied before resorting to any form of collapse therapy.

Cavities may be classified as:

(a) *Acute* recent progressive walls soft irregular poor or no drainage pericavitary zone of infiltrating edematous exudate.

(b) *Subacute* fluctuating walls soft and thin of indefinite outline enclosing varying amounts of necrotic and devitalized tissue debris exudate and pus irregular drainage the pericavitary zone clearing and showing beginning fibrosis.

(c) *Chronic* stationary well defined thick fibrotic or rigid walls fair to good drainage pericavitary zone of condensing fibrosis.

The character and extent of lesions in the pericavitary zone are of prime importance in the formation, limiting and healing of the

cavity proper. They are of equal importance in determining the form of collapse therapy.

Cavities under favorable conditions may heal spontaneously—by absorption drainage and contracting fibrosis. The amount and density of fibrosis is the most reliable index of local resistance and a natural tendency to heal. Obliteration is facilitated by compensatory expansion and emphysema of the elastic lung parenchyma surrounding the cavity. These necessary factors are most often present in early mid lung cavities.

When the anatomic and physiologic limits of contraction are reached further contraction is checked by mechanical factors. Contraction may be prevented by organization of the pericavitary fibrous tissue into dense retracting bands extending into the depths of the lungs to the interlobar fissures or to the hilum where the anatomical arrangement of bronchi, pulmonary vessels and lymphatic structures normally forms a denser area than farther out in the lung.

Multiple cord or band adhesions tethering the cavity, contracting unyielding broad adhesions to the chest wall or diaphragm exert continuous tension on the peripheral area of the lung and any cavity it may contain. This contraction while fairly constant has a tendency to increase as the adhesions become fibrous and stronger. The alternating tug and relaxation exercised by the inspiratory and expiratory excursions of the thoracic wall and diaphragm keep the pleura, the lung, the pericavitary zone and the cavity in a state of irritative activity. This state of unrest is inimical to contraction and healing of the diseased area.

The cavity will migrate or shift in the direction of the strongest pull—toward the most fixed point.⁶ In the upper lung field it will be drawn toward the apex of the thorax where on account of the anatomical relations adhesions are usually diffuse and firm. In the superficial lung field near the visceral pleura adhesions will draw it to the chest wall. In the mid lung area fibrous bands will draw it to the hilum or mediastinum. Near the base it becomes fixed to the diaphragm.

When bands of fibrosis or adhesions extend in nearly opposite directions from the cavity and pull on the walls with almost equal force the cavity becomes suspended

between these two opposing forces. A suspended cavity cannot be healed until one or the other or both restraining factors are relaxed. The contracting fibrosis in a chronically diseased lung which is diffusely adherent to the lateral chest wall draws the adherent mobile mediastinum and its contents toward the diseased side until the limits of contraction are reached.

A progressive or uncontrolled cavity is a surgical condition and demands some form of collapse therapy to secure compression and healing. The principle of collapse therapy by any procedure is the same; the only difference being in technique and degree. The less drastic method should be tried first.

Suction drainage of tuberculous cavities is an improved method of direct attack on cavernous lesions.³²

The rationale of the method includes cleansing the cavity of retained secretions and necrotic debris, leaching the edematous infected cavity wall and pericavitary zone and producing re-expansion and aeration of the immediate pericavitary atelectatic lung tissue by means of negative intracavitary pressure secured through moderate intermittent suction.

The indications for suction drainage are limited: cavities with elastic, thin or non-rigid wall without much infiltration or fibrosis; a pericavitary atelectatic lung field. The cavity must be near the visceral pleura. The overlying pleural space must be obliterated or pleural symphysis must be obtainable. The cavity must be near to and approachable through a related intercostal space.

The cavity proper is not or only partially drained. It is filled with secretion or necrotic debris which can be neither expelled nor absorbed. The inadequately draining bronchi are kinked partially or completely stenosed or obstructed by a check valve cut-off.

The cavity must be accurately located and oriented in relation to the chest wall and intercostal space. Under fluoroscopic guidance a special aspirating needle fitted with a three-way stopcock and graduated so as to indicate the distance the cavity lies from the thoracic wall is introduced through the related intercostal space. One cock is connected with a manometer to check pres-

sure fluctuations of a free pleural space which if present must be obliterated before proceeding and to indicate the entrance of the needle into the cavity. The other cock is connected with a small syringe and some of the contents are aspirated to make certain the cavity has been entered. The direction and depth of the needle are noted. The needle is withdrawn and through the course taken by the needle a trocar cannula with a manometer hook up is introduced to the proper depth in the cavity. Pressure readings are then taken. The mandrin is withdrawn and a snugly fitting catheter is passed through the cannula into the cavity. The cannula is then withdrawn leaving the catheter in place. The next day mild suction is begun and continued intermittently until the catheter extrudes itself or the cavity is shown to have become obliterated by a chronologic series of x-ray films. It may take months before obliteration is secured. The technique is not so difficult as is the proper selection of cases. Suction drainage in a number of properly selected cases has effected dramatic improvement. Unfortunately the improvement is frequently only temporary.

Suction drainage focuses attention on the cavity. It does not take into consideration the pericavitary zone and surrounding area, the common sites for the chief impediment to obliteration of cavities. Cavities treated by suction drainage almost invariably demand supplementary surgical compression by thoracoplasty.

Collapse Therapy—Collapse may be accomplished by artificial pneumothorax—unilateral, alternating or simultaneous bilateral.⁵ Temporary or permanent interruption of the phrenic nerve and direct or indirect intrapleural pneumonolysis are operations which relax the lung and leave the bony thoracic wall intact. Scalenotomy, extra-pleural pneumonolysis with or without filling the pocket and partial upper partial lower or complete thoracoplasty are operations for compression by altering the bony thoracic wall.

Artificial Pneumothorax—Artificial pneumothorax¹ lessens the volume of the lung by the injection of controlled amounts of air through a needle introduced into a free pleural space. It may be relaxing or

mildly compressive. The technique is standardized. There are a few unavoidable hazards connected with the induction and some complications attending the continuance of the treatment. Refills are necessary at more or less regular intervals over a long period of time—sometimes years.

Early continuous moderate relaxing pneumothorax is a prophylactic pneumothorax. It separates the visceral from the parietal pleura, prevents early formation of adhesions, relaxes and rests the lung and is conducive to collapse of early soft thin walled cavities and to the healing of the pericavitary zone and other lesions in the lung. Early pneumothorax may render further measures of collapse therapy unnecessary.

The practice of inducing pneumothorax to rather high degrees of plus pressure in order to secure an increasing degree of compression of the lung or to attempt rapid attenuation of restraining adhesions as desirable as this may be frequently causes even when carefully watched unpleasant or even serious complications. Slow attenuation with low positive pressure is safer though less effective.

Complications of pneumothorax are pleural shock, air embolus, serous effusion, tearing of adhesions, rupture of a superficial cavity, hemorrhagic, tuberculous or purulent effusion, pyopneumothorax and pulmonary pleural fistula.

When an efficient pneumothorax is induced and can be continued without lapse for the required length of time, it is the most effective form of collapse. Collapse to be fully effective must completely and continuously relax or compress the predominantly diseased area.

On account of adhesions or obliteration of the pleura a pneumothorax cannot always be induced and maintained to a degree necessary to relax the diseased or cavity-bearing area. A patient with a successful pneumothorax may become negligent. Progressive development of advancing adhesions gradually converts an efficient to an inefficient pneumothorax. An incomplete pneumothorax while it may not collapse a cavity does exercise a salubrious effect on the pericavitary area; it renders the pleura less sensitive and the mediastinum more rigid.

and gives the heart and opposite lung time to become somewhat adjusted to the altered intrathoracic pressure. One must not be deceived by this amelioration. In the absence of continuing improvement in the local lesion and collapse of the cavity the patient thus fortified will better tolerate more formidable procedures for collapse. These should be instituted without further delay.

Moderate experience with artificial pneumothorax should enable one to appreciate its value as well as its limitations. Too prolonged treatment without diminution in the size of cavities or continuing improvement of lesions in the lung is not good therapy. It is a waste of valuable time, it courts complications and withholds from the patient other measures when these give assurance of benefit.

Intrapleural Pneumonolysis—*Closed intrapleural pneumonolysis* is the severance of restraining pleuritic adhesions through a thoracoscope by means of an electric cautery or by electric coagulation.

In *open intrapleural pneumonolysis* the pleura is opened and the adhesions are cauterized, coagulated or doubly ligated and cut.

Pleuritic adhesions are the greatest impediment to successful artificial pneumothorax. They may be prevented by early induction. If restraining adhesions are narrow cord, band or fan shape and long enough to permit manipulation of the necessary intrathoracic instruments they may be severed by intrapleural or closed pneumonolysis.¹⁰ Thus may an inefficient or partial pneumothorax be made efficient and complete. Intrapleural pneumonolysis has been improved and made safer and its field broadened.¹¹

Exponents of the thoracoscope advocate its use for intrapleural orientation of the size, character, number and length of adhesions.¹²

Adhesions may be thin, thick, short, long, cord, band, broad or fan shape. They may contain attenuated lung tissue or bronchioles with or without tuberculous involvement. Vascularization is superficial or central.

The character of the adhesions and their relation to the tuberculous cavity, lung, pericardium, large vessels (especially at the apex) and thoracic wall are of great impor-

tance not only in the effect they exercise in keeping the cavity and lung expanded but also in the possible danger of puncturing important structures and tearing or erosion of the cavity wall or diseased lung during or subsequent to cautery pneumonolysis.

The type, number and character of adhesions cannot be accurately determined by x-ray study. Their restraining effect must be established before intrapleural severance is undertaken and the reaction it will induce on the diseased area and in the remainder of the lung should be estimated.

In the apex of the thorax, where intrapleural pneumonolysis would be most helpful it is frequently impossible or too dangerous.¹³

Intrapleural pneumonolysis is an ideal procedure in expert hands for the comparatively few cases in which the operation is indicated.

The complications of intrapleural pneumonolysis are serous to purulent effusion, hemorrhage into the free pleural space, erosion of the lung, pericardium or great vessels, perforation of the cavity, section of parenchymal tissue extending into adhesions, pyopneumothorax and bronchopleural fistula.

Interruption of Phrenic Nerve Conduction—Interruption of the conduction of the phrenic nerve was first performed by Stueritz.¹⁴ The exhaustive study of Felix in 1922 established the rationale of the operation.¹⁵ The purpose of interruption of the phrenic nerve is to secure physiologic rest of the lung by paralyzing the corresponding half of the diaphragm.

The effects include paralysis of the diaphragm so that it becomes entirely passive. Any movement it may make and any position it may assume are dependent on the relative intrathoracic tension above as determined by pleuritic adhesions, dense massive or contracting fibrosis of the lung, fluid or air in the pleural space and the influence of the intra-abdominal pressure below the diaphragm. It loses its normal tone and movement. The piston like up and down action with each respiratory cycle particularly the inspiratory phase at the base of the lung is stopped. Aspiration and stasis of secretions and pneumonia are prevented. There may be paradoxical movement but

this is of comparatively minor consequence. The diaphragmatic muscle atrophies and unless held by diffuse adhesions in the costo phrenic angle soon begins to rise. Tugging of adhesions and retracting bands of fibrosis extending upward from the base of the lung toward the hilum and apex is relaxed. The average rise is slightly greater on the right than on the left side. The maximum elevation may not be reached for months. The volumetric capacity of the thorax is reduced one sixth (400 cc) or one third (800 cc).

The relaxing effect on lesions in the upper lobe is almost as great as in the lower lobe unless diffuse adhesions interfere. Apical cavities where diffuse adhesions are the rule are not usually affected. Subapical and infracavicular lesions and cavities are more

phatic is minimized. The paralyzed diaphragm offers little resistance to the intra abdominal pressure. The unimpeded upward force of the abdominal pressure makes coughing easier and more productive hence less frequent. The diminution of respiratory activity of the lung on the operated side increases the amount of work of the contralateral lung and tests its capacity to assume the burden of respiration.

The Result—Interruption of the phrenic nerve produces continuous uniform relaxation of the lung without the inconvenience or dangers of frequent pneumothorax refills. It places the lung in a state of partial rest so that it can improve more rapidly and surely. The time of antituberculous residence is reduced.

Fig 487—*a* Large thin walled allent cavity in the right upper lobe. Extensive mixed exudative type of lesion to the middle and right lower lobe. A similar type of lesion in the opposite lung. *b* After phrenic nerve interruption. Marked elevation of right half of diaphragm displacing the heart. Contracting fibrosis of lesions in the middle and lower lobes interferes with drainage of the cavity.

often than not benefited, or healed. Very rarely conditions may be made worse (Fig 487).

Gaseous interchange within the lung is diminished. The circulation of the blood and lymph is retarded. By this stasis the toxins within and about the lesions are kept more localized. The absorption of air or fluids from within the pleural space may be restricted. This is of importance in artificial pneumothorax. The necessity of refills may become less frequent. Intrapleural tension being reduced adhesions relaxed and the diaphragm elevated the collapsing effect of an equal or lesser volume of introduced air becomes more selective. The danger of com-

Phrenic nerve operations—crushing (phrenic emphysema), cutting (phrenic neurectomy) and avulsion (phrenic excision) because of their simplicity have been abused. They are not and never were intended to be complete or curative operations. Collapse and healing of cavities does occur occasionally. The improvement in both local and general conditions is striking but only too often temporary. Much valuable time and many favorable opportunities are wasted by not taking advantage of this temporary gain to resort to other procedures for collapse.

Paralysis of the phrenic nerve may be temporary or permanent. For temporary paralysis the main phrenic nerve is crushed

and all the access-ory branches are cut. This paralyzes the diaphragm for about three months. The crushing may be repeated so as to continue the paralysis. It is a valuable adjunct to controlled collapse therapy and should be used earlier and more frequently than is now the custom.¹⁶

For permanent paralysis not less than 4½ or 5 inches of the main trunk of the phrenic nerve must be avulsed from within the

(1) in a case of acute involvement of a lower lobe or mid-lung or a case of acute, diffuse unilateral disease; (2) when there are thin-walled, superficial, basal, mid-lung or infraclavicular cavities with a pericavitary zone of exudative type; (3) when it is desired to obviate the necessity or inconvenience of pneumothorax refills; (4) when pneumothorax is impossible or minimal or the patient is uncooperative; (5) when only

Fig. 488—*a*, Extensive bilateral, long-standing fibrosis. There is a large multilocular cavity in the upper lobe of the left lung; *b*, after phrenic excision the diaphragm rises markedly and the cavity is smaller; *c*, progressive diminution in the size of the cavity; *d*, the cavity has disappeared. Phrenic nerve interruption was performed as a preliminary to thoracoplasty. The patient improved rapidly and has remained symptom-free for over a year.

thorax. This will usually sever the anastomosis of the accessory branches (present in 20 per cent of cases) which join the main nerve along its course to the diaphragm. Occasionally one or more accessory nerves may have an independent course to the diaphragm. Therefore in doubtful avulsion of the main nerve *c*, all accessories should be cut.

Indications for phrenic nerve interruption: Temporary interruption is indicated

an upper stage thoracoplasty or apicolysis is contemplated for resistant lesions of the upper lobe with copious expectoration and a temporary pneumothorax to control the lower lobe is impossible; (6) in case of bilateral disease requiring simultaneous bilateral or alternating compression (a pneumothorax is given on the side of the greater involvement and a crushing of the phrenic nerve is performed on the other side), and

(7) for persistent singultus (accomplished by means of bilateral injection of alcohol into the main nerve)

Permanent interruption is indicated (1) as a substitute for or a supplement to pneumothorax especially if partial incomplete or unsatisfactory (2) as a sequence to pneumothorax to taper off the collapse and limit full re-expansion of a compressed or fibrotic lung (as much care must be exercised in abandoning as in beginning a pneumothorax (3) supplementary to thoracoplasty in order to increase the compression (4) when the severity of the disease precludes thoracoplasty (5) for severe or repeated hemoptysis not otherwise controlled (6) to relax the lung and favor closing of a pulmonary pleural fistula (7) to reduce the size of empyema cavities (8) to reduce the capacity of the thorax after lobectomy (9) for bronchiectasis of a lower lobe (10) as a palliative measure to relieve severe exhausting painful cough and (11) as a preliminary to operations for diaphragmatic hernia

Complications of operations on the phrenic nerve include hemorrhage or air embolus from the tearing of the large veins in the neck or of one of the arteries especially the transverse cervical injury to the thoracic duct mediastinitis resulting from the opening of an infected vein or a caseous focus mediastinal hemorrhage emphysema from tearing and adherent lung pericarditis damage to the sympathetic plexus in the neck sectioning other nerves mistaken for the phrenic nerve (the recurrent laryngeal vagus or a branch of the cervical plexus) and prolonged gastric disturbance due to the shifting of the stomach and duodenum

Some authorities state that paralysis of the diaphragm suppresses the physiologic activity in the lower portion of the lung and reduces the respiratory excursions of the lower thorax. The unopposed action of the scalenus and upper intercostal muscles compensates for this inhibition by increasing the activity of the thorax above the fourth rib. If an increase in the transverse diameter and in the excursions of the upper thorax did occur it would unfavorably influence the lesions in the upper lobe.¹⁷

Scalenotomy—Scalenotomy is an operation in which all the scalenus muscles—the

anterior, medius and posterior—are severed close to their insertions on the first and second ribs.¹⁸

The purpose of scalenotomy is to eliminate the action of the scalenus muscles and secondarily to limit the action of the upper intercostal muscles on the upper four ribs.

The effect is conducive to contraction of the upper thorax especially in the transverse diameter and relaxation of the apex of the lung. When the diaphragm is paralyzed the unopposed scalenus muscles tend to overact and cause a compensatory hyperactivity of the upper thorax. A simultaneous scalenotomy or one subsequent to interruption of the phrenic nerve prevents this and augments the relaxing effect of the paralyzed diaphragm.

The Result—The degree of contraction of the upper thorax and the relaxation of the apex of the lung are often negligible and disappointing. Some authorities claim that this contraction may amount to 40 per cent.¹⁹

Extrapleural Pneumonolysis—Extrapleural pneumonolysis termed apicalysis by Friedrich when limited to the apex of the lung is an open operation by which a cavity and its surrounding lung area are actively compressed. The endothoracic fascia is separated from the under surface of the thoracic wall overlying the area of the cavity. After the cavity is compressed the resulting subcostal space or pocket is usually filled with some material to maintain the compression.

Extrapleural pneumonolysis is designed to secure a highly selective compression. Were it not for a number of disadvantages it would be ideal. Firm fusion of the endothoracic fascia to the ribs, rupture of the cavity or hemorrhage make completion of the operation impossible. The pneumonolysis is not always efficient; it is less certain and only slightly if at all less serious than a limited thoracoplasty. No satisfactory filling material has been discovered. Gruze must be replaced frequently; fat liquefies, muscle atrophies and contracts; the amount available is limited and the opening for incision is necessarily large.²⁰ Air requires refills.²¹ A hydrostatic bag requires a projecting tube which invites infection and paraffin is irritating and heavy though recommended by some workers. All of the

materials have inherent disadvantages. Introduction of any foreign material leads to irritation, effusion and occasionally the development of infection within the pocket. The material may shrink or shift and the cavity may re-expand. The cavity wall may undergo pressure necrosis, infect the pocket and discharge externally, causing a bronchial fistula. The filling material may per-

approach its effectiveness in compressing resistant residual cavities especially those in the co-stovertebral groove which a corrective thoracoplasty has failed to close.

Indications include small or medium sized chronic fibrotic apical cavities with a pericavitary fibrotic zone, thick overlying pleura, an obliterated pleural space, the remaining portion of the lung being free of dis-

moderate and delayed effects. It is little if any more selective and more prone to complications. postoperative convalescence is slower than after total subperiosteal resection of the upper three ribs.

Extrapleural pneumothorax (subfascial pleurolysis) a subendothoracic fascial space coextensive with the underlying pulmonary area containing the cavity is made by blunt dissection. The space is then kept filled by means of injections of controlled volumes of air. The approach is through an incision in the periosteal bed of the resected (1 or 2 inch segment) rib overlying the cavernous area. The endothoracic fascia is identified and the line of cleavage between it and the

cure and maintain collapse of the cavernous lung area are begun and continued until the cavity closes or the space becomes obliterated. Injections of oil may later be substituted for the injections of air.

Extrapleural pneumothorax is similar to extrapleural pneumonolysis with the exception that only a short segment of one rib is removed. Its advantages are that it is less drastic, less shocking and hence well tolerated. Therefore it may be performed on patients who are very ill or who have bilateral cavitation and could not withstand extrapleural pneumonolysis or multiple stage limited thoracoplasty. The disadvantages are those of incomplete operations: it re-

Fig. 490—A Operation of the Seled type in which small segments are resected from the lateral aspect of the thorax. The posterior stumps spring outward a black arc and tend to increase the depth and area of the costovertebral groove. B More extensive resection from the posterolateral aspect of the thorax. The shorter posterior stumps still interfere with compression in the costovertebral groove. C Adapted from the original H. G. Gourlet. Thoracoplasty Posterior. A comparatively short segment of the rib as resected. The collapsing effect is much better. D Extensive resection from the transverse space process for and almost to the costal cartilage. The costovertebral groove is almost obliterated. The collapse of the lung is very satisfactory.

ribs is carefully followed by blunt dissection working from the under surface of the ribs rather than from the visceral surface to avoid rupture of the cavity or the lung. A subfascial space is made extending widely beyond the known limits of the cavity bearing area of the lung. Absolute hemostasis must be secured by temporary packing with strips of hot moist gauze. The overlying soft parts (periosteum, muscle, fascia and skin) are accurately sutured in layers thus sealing the subfascial space which is then filled with air under low positive pressure. When the wound becomes firmly healed periodic refills of air manometrically controlled to a moderate degree of positive pressure to se-

quires a prolonged course of air refills; the results are uncertain and there is danger of hemorrhage, immediate operative or delayed rupture of the cavity and intractable or serious infection of the space. It violates a cardinal surgical principle by creating a closed space which may fill with serum or blood. A dead space is prone to infection. It may be performed as a preliminary stage to but not as a substitute for extrapleural pneumonolysis or limited thoracoplasty. Patients are rarely seen who present indications for surgical collapse who conditions give promise of amelioration or cure and who cannot tolerate other procedures for surgical collapse when performed in very

limited stages The advantages are much more theoretical than practical

Lobectomy—Lobectomy to eradicate cavity tuberculosis confined to a single lobe has been successfully performed The predominant lesion may be confined to a single lobe It is rarely if ever the only focus Lobectomy is a very formidable operation and the manipulation necessary to free and remove the diseased lobe is fraught with danger of causing widespread dissemination If the remaining lobes are adherent compensatory expansion to fill the intrathoracic space remaining after lobectomy will not be complete The dead space can become a hazard particularly if it becomes infected It must then be obliterated by a thoracoplasty Lobectomy has been performed for the type of cases that have been and can be so successfully treated by the far less drastic operation of limited thoracoplasty

Thoracoplasty—Thoracoplasty is the subperiosteal resection of definite lengths of a number of ribs to secure compression of the diseased area and the obliteration of cavitation It may be partial (limited to the upper or to the lower ribs) or complete

Partial thoracoplasty implies the resection of segments from a few ribs complete thoracoplasty implies resection of segments from the first to the eleventh ribs inclusive Complete thoracoplasty in a single stage is most effective and uniform in its compression but the mortality is prohibitive The excessive mortality has led to the performing of multiple stage operations resecting a few ribs in each stage²³ This has reduced the mortality and extended the field of surgical compression to include the greatly debilitated patients

Total or subtotal resection of the upper three or four ribs exercises a remarkably efficient and decidedly selective compression on the upper lobe The lower lobe is not materially affected⁴ The collapsing effect of rib resection depends not so much on the length of the segment removed as on the shortness of the remaining stump The number and length of rib segments to be resected are determined by the character extent and localization of the disease in the lung the stability of the mediastinum the thickness of the pleura and the conformity and rigidity of the chest wall Parsi-

monious resection secures only partial collapse and leaves uncollapsed and residual cavities which demand secondary operations Lateral costectomy²³ anterior costectomy or difficult corrective operations Cavities especially those in the costovertebral groove that are not completely compressed by an extensive extrapleural posterior thoracoplasty or by a corrective operation may be obliterated by extrapleural pneumonolysis and gauze tamponade

Extrascapular apicectomy or pneumonolysis first performed by Carl Semb²⁷ of Oslo secures concentric collapse and contraction of the entire cavity bearing area of the upper part of the lung almost to the level of the hilus In this operation resection of the upper rib segments is not so extensive as in the total subtotal or Alexander type of thoracoplasty The extrascapular ligamentous attachments and adhesions to the lower cervical nerve roots to the large vessels and to the anterior and the posterior mediastinum are carefully severed by sharp and gauze dissection The entire dome of the pleura is freed and then depressed Semb reports collapse of 90 per cent of the cavities with a mortality of 3 per cent²⁸ Alexander²⁹ reports 96.5 per cent closures with posterior plus the Haight type of anterior thoracoplasty Overholt³⁰ shows beautiful plates of the ligamentous attachments and restraining adhesions in describing his technique of mobilization of the lung In practice these are rarely if ever so clearly delineated in the chronic fibrotic cavity bearing lung in which this operation is ideally indicated In these cases the fusion is broad practically continuous throughout the upper lobe Mobilization of the dome of the pleura is best effected by blunt and gauze dissection beginning in the plane along the lower border of the lowest root of the cervical plexus (the eighth) as close to the spine as possible From this point one proceeds forward along the sheath of the subclavian vessels using sharp dissection for the denser bands of tissue The second intercostal muscle bundle is cut close to the spine after ligation of the intercostal vessels The ligament and adhesions to the posterior mediastinum are then severed The adhesions to the anterior mediastinum are then separated Extrascapular pneumonolysis may be performed at the

first upper stage or may be a step in a revision or corrective operation for collapse of resistant cavities. The latter is a more difficult but safer procedure.

With total or subtotal resection of the upper ribs collapse of apical and subapical cavities is more efficient and residual cavities are less frequent than with the resection of the limited segments of the former types of thoracoplasty.

ribbed upper portion of the thorax cannot be adequately supported. On coughing paradoxical expansion of this unsupported lung is inimical to clearing the secretion from the diseased area.

When all efforts to close residual cavities have failed open drainage is indicated. In the early primary selective opening drainage and treatment of cavities no consideration was given to the pericavitary lesions

Fig. 491—*a* The patient lies on the operating table with the head low. The arm abducted by an assistant, is pulled slightly forward carrying the scapula with it. An incision is made midway between the vertebral border of the scapula and the spinous processes of the vertebral column beginning opposite the spinous process of the second dorsal vertebra. It extends downwards parallel to the spine and then curves around the angle of the scapula almost to the anterior border of the latissimus dorsi muscle. *b* (Adapted from A. Brunner, *Tuberculose Bibliothek*) Showing direction of the needles for blocking the intercostal nerves. *c* Showing the depth to which the needles are inserted in order to instill the novocain solution into the pectoral space.

Extrascapular pneumonolysis is indicated for apical and subapical cavities with dense fibrotic pericavitary zones without exudative foci.

The manipulation incident to mobilization of the lung is too sudden and massive compression of an actively diseased area of the lung is fraught with the danger of local or widespread dissemination of the tuberculous process. The unsupported mobilized area of the lung beneath the limited de-

pressed upper portion of the thorax cannot be adequately supported. On coughing paradoxical expansion of this unsupported lung is inimical to clearing the secretion from the diseased area. When all efforts to close residual cavities have failed open drainage is indicated. In the early primary selective opening drainage and treatment of cavities no consideration was given to the pericavitary lesions. Extrascapular pneumonolysis is indicated for apical and subapical cavities with dense fibrotic pericavitary zones without exudative foci. The manipulation incident to mobilization of the lung is too sudden and massive compression of an actively diseased area of the lung is fraught with the danger of local or widespread dissemination of the tuberculous process. The unsupported mobilized area of the lung beneath the limited de-

drainage the duration and severity of the constitutional toxic symptoms caused by this blocking and the absorption of toxins from the closed cavity must be balanced against the inconvenience of a prolonged and possibly a permanent external fistula.

Indications for Thoracoplasty—If the contralateral lung is capable of maintaining the respiratory function then thoracoplasty may be considered. The same general indications obtain as for pneumothorax when this cannot be induced or continued or is unsatisfactory when after a successful

its against mediastinal flutter and cardiac displacement.

Other indications for thoracoplasty include repeated severe bleeding from a cavity that cannot be relieved by other measures, unsuccessful extrapleural pneumolysis, marked fibrosis compressing and embarrassing the heart, empyemas either tuberculous or the mixed infection type which are not controlled by aspiration, irrigation, closed drainage or adequate open drainage, pyopneumothorax with or without bronchial fistula and bronchiectasis. Old

Fig. 492—Upper stage thoracoplasty. The muscles have been severed. The scapula has been elevated from the ribs and retracted forward and upward. The second to sixth ribs are exposed. The deep-lying first rib overlapped by the second rib cannot be seen until the origin of the serratus anterior muscle has been freed. The periosteum of the second rib is being raised. The intercostal muscles to the third rib are being stripped from behind forward along the upper border and from before backward along the lower border. The Doyen rib stripper is freeing the fourth rib from its periosteal bed. The retraction of the spinal muscles is exposing the neck of the fifth rib with its ligamentous and muscular attachments.

pneumothorax lesions in the re-expanding lung become active or when the lung fails to re-expand after pneumothorax.

Thoracoplasty is indicated if there are predominantly unilateral chronic fibrotic lesions either with or without cavitation and if other forms of therapy and less drastic measures for collapse have been tried and have failed or cannot be expected to succeed. The degree of fibrosis and contraction deformity is a reliable index not only of the local resistance but also of the stability of the mediastinum. A rigid mediastinum gives assurance of cavity collapse and is a secur-

chronic inactive foci or foci of low grade activity with or without cavitation in the contralateral upper lobe near the apex do not constitute contraindications.

Contraindications—Active fresh or recent lesions in the opposite lung especially near the base, severe asthma, emphysema, an active or decompensated diseased heart, uncontrolled diabetes and severe disease of the kidneys are absolute contraindications. Tuberculosis in other organs according to the degree of activity is an unfavorable complication which prejudices but does not preclude surgical collapse unless very ex-

tensive. Severe anemia, a low hemoglobin content and a rapid pulse rate are warnings of danger.

The bulk of the patient is in some way associated with the myocardial reserve. The heavy-muscled, soft, fat, flabby, full-chested type of patient gives a deceptive impression of strength but is surprisingly intolerant of surgical intervention. The lean, small-

pressure may give some idea of the myocardial reserve.

Since most of the operative and immediate postoperative and some of the delayed deaths are directly or indirectly associated with a myocardial deficiency, it is of the utmost importance not to overtax the heart. In the absence of any reliable test of the cardiac reserve, one must guard against at-

Fig 493—c, Large upper right cavity and activity of the lesion in the lower lobe, controlled by phrenic nerve interruption. There is moderate deformity. The contour of the shoulder posteriorly can be preserved if the incision is not extended so high as b and d. After thoracoplasty in three stages and a corrective operation there is still some activity in the lower lobe that is not controlled by the phrenic nerve and that demands further operative collapse.

chested, light-muscled patient is more tolerant of operations of equal or greater magnitude.

Dangers of Thoracoplasty.—The condition of the cardiovascular system, especially the capacity of the myocardium, is one of the most difficult and important factors to estimate. Mild exercise tests, ability to hold the breath, the effect of slow digitalization on the rapidity of the pulse and the blood

tempting too much in any operation. Far better to regret doing too little and have the patient react well than to attempt too much and have the patient die.

The heart is unfavorably influenced postoperatively by (a) shifting with the mediastinum by rotating and sinking in the altered thorax; (b) alteration of the intrathoracic support, especially by the lungs²⁶ (care must be taken to avoid compressing

the heart by removing too much of the anterior ends of the fourth, fifth and sixth left ribs over the cardiac area); (c) sluffing, angulation of and pressure on the great vessels at the base of the heart, especially on

coughing, straining and deep or forced breathing, residual air accumulates in the unsupported area in direct ratio to the force of the expiratory effort of the other lobes and the contralateral lung

Fig 494—*a* Predominant right-sided involvement. There is a large multilocular apical cavity and some low-grade infection of the lower lobe. Pneumothorax is not possible. *b* After subtotal upper stage thoracoplasty. The entire first rib, $4\frac{1}{4}$ inches of the second, $4\frac{1}{2}$ inches of the third and 5 inches of the fourth rib have been removed. The cavity is obliterated, and the lower lobe is clearing. The case is clinically symptomless.

the right side; (d) increase of the resistance in the pulmonary circulation consequent to compression of the pulmonary vessels and loss of the pump action and rhythmic changes in the intrapulmonary pressure; (e) reduction of pulmonary aeration causing dyspnea, anoxemia and general circulatory embarrassment, (f) pleuropericardial adhe-

Secretions accumulate and may be expressed into adjacent lobes or the bronchi of the opposite lung. Atelectasis, spread of infection or pneumonia may develop. Dyspnea, anoxemia, cardiac deficiency, peripheral circulatory paralysis and death may ensue.

To obviate this vicious circle, too extensive de-ribbing must be avoided. The de-

Fig 495—*a* Inadequate collapse after multiple stage thoracoplasty with residual cavities. *b* after a corrective operation through the scar of the original incision. The anterior stumps and the regenerated ribs were removed. The remaining adherent fragments of regenerated ribs are visible.

sions and scars with more or less fixation of the heart, (g) unbalanced volumetric interchange of air between the two lungs, and (h) modification of the extrapleural pressure, especially if too great and precipitate.

The unsupported de-ribbed area cannot participate in normal respiration. During

ribbed area must be supported immediately and for some weeks after operation. Adequate adhesive strapping, leaving the opposite side of the chest free, is necessary. Should respiratory difficulty develop, early inhalation of oxygen or the oxygen tent is indicated.

Shock, intimately associated with cardiovascular embarrassment, is to be guarded against by careful preoperative preparation. During operation too much should not be attempted in any one stage. Hemostasis must be meticulous, the tissues must be handled very gently, and the area must be kept warm, covered and supported by saline packs. After operation the body must be kept warm, the foot of the bed must be elevated on blocks and the patient should be given cardiac stimulation, early oxygen inhalations, dextrose or timely blood transfusions of moderate amounts, repeated as often as indicated.

Some surgeons perform the lower stage operation first. They claim that the over-

The time permitted to elapse between stages varies with the progress of the patient. The shorter the interval, the more uniform will be the compression. A good rule is to allow a sufficient interval for the patient to recover, to permit the heart and the lung to become adjusted to the altered conditions and for the compressed lung area in a measure to clear itself. A first lower stage operation does not produce as great a degree of collapse as a first upper stage operation. If the lower stage is followed too closely by an upper stage operation, the compressing effect of the combined operations may be so great as to cause serious, if not fatal, cardiac or respiratory complications.

Fig 490—*a*, Multilobular cavitation involving the entire upper left lung Pneumothorax which controlled the pencavitary lung fields and improved the general condition of patient, was greatly diminished by progressing adhesions *b*, Upper stage thoracoplasty cavities are greatly reduced Pneumothorax to control the comparatively good condition of the lower lobe is being continued The trachea is displaced to the opposite side *c*, The cavities are obliterated The lower lobe of the lung is allowed to re-expand gradually

flow of secretions into and infection of the uncompressed lung area is thereby minimized, the cough reflex is not greatly inhibited and the cough is more effective. Other equally good surgeons perform the upper stage first for the same reasons.

When the upper stage is performed first, the lower lobe, if free or lightly diseased, may be controlled by a partial pneumothorax, which must be reduced just prior to operation. If a controlling pneumothorax is impossible, a temporary or permanent interruption of the phrenic nerve may be performed. The most logical procedure is to compress the most diseased area at the first operation, thereby securing a greater improvement in the local and general conditions. The disease may be so effectively controlled that unless extension takes place a second stage may not be necessary.

For the very ill patient whose resistance is so low and his reaction to any type of surgical procedure so decidedly poor that the usually well tolerated limited posterior thoracoplasty would be extremely hazardous. Wangenstein²¹ recommends multiple stage osteotomy.

For the first stage there is an anterior approach through a short transverse incision over the second rib. The pectoral muscles are not cut but are split in the direction of their fibers. The second rib is exposed, and a 3 inch segment is resected subperiosteally, together with its cartilage. If the incision is retracted up and down, anterior segments of the first and third ribs and cartilage may also be removed. There is little bleeding, with very little shock. The wound is closed. A week or ten days later, the second stage is performed. With a posterior approach

through a short oblique paravertebral incision the heavy muscles of the back are split in the direction of their fibers. The posterior ends of the same ribs whose anterior ends were severed in the first stage are cut close to the spine and the entire rib segments are removed subperiosteally from behind. A week or two later the same sequence first an anterior then a posterior stage on the next lower ribs may be repeated three or four ribs being sectioned in each step. This plan a modification of an old empyema operation is excellent but its execution in even better than average hands is far from easy. In the posterior stage the rib must be separated from its periosteal bed on the lateral aspect of the thorax by a modified tunneling procedure.

In old fibratic cases nature's effort at contraction of the thorax causes the ribs to approximate and occasionally to overlap. Their resection under these circumstances is difficult by the usual posterior paravertebral approach in which the ribs are in full view. With meticulous hemostasis gentle handling of tissues and the avoidance of doing too much at any one stage there will rarely be a patient so ill that he cannot be operated on with reasonable assurance by posterior paravertebral thoracoplasty.

Statistics of different surgeons on the results of surgical treatment are not comparable unless the type extent stage and duration of involvement of the lung and the general condition of the patient are considered. The slower the disease develops the better are the chances for the opposite lung to compensate for the respiratory deficiency and the higher is the grade of resistance. Therefore in the very young and the adolescent patient the disease does not usually warrant surgical procedure. On the other hand in patients over fifty with long standing disease the organs are so compromised by toxins and the effects of the wear and strain of life that they are not often able to withstand a severe operation. Between these decades operation offers in a large group of resistant or advanced cases the only chance of amelioration or cure.

Over 37 per cent of surgically treated patients have been clinically cured 25 per cent have been decidedly improved. The immediate and delayed mortality is approximately 15 per cent.⁴

XXIII. THE HEART AND PERICARDIUM

SURGERY OF THE HEART AND PERICARDIUM

COMPRESSION OF THE HEART

Physiology—Under normal conditions the heart and the great blood vessels are exposed to a pressure less than that of the atmosphere. This negative pressure within the pericardial and mediastinal cavities is produced by the elastic recoil of the lungs and measures about 5 to 8 cm. of water. The venae cavae and right auricle also carry a negative or sucking pressure. A delicate pressure relation exists between the pressure outside and the pressure inside these venous channels. If the pressure outside the venae cavae and right auricle is increased by a few centimeters of water these structures are temporarily collapsed (Fig. 497). Blood is dammed back in the venous channels until it accumulates sufficient pressure to break through this barrier of pressure from the outside. Then the circulation starts up again and the blood enters and is expelled from the heart. If another increment of pressure is applied to these venous channels the obstruction is repeated and the pressure within the venous channels again must rise to a higher level in order to break through the additional barrier. This play of pressures can continue until the pressure within the venous channels can no longer rise above the pressure from without. When this level is reached the circulation comes to a complete standstill. At all times the pressure within the venae cavae and the right auricle must be higher than the pressure outside these structures. The venous pressure can rise to about 16 cm. of water; thus can be considered as the approximate fatal level for intrapericardial or mediastinal pressure developing acutely. If the pressure develops slowly over a period of days or weeks the venous pressure rises to greater heights (42 cm. of water). Such a high venous pressure is a protection against compression of the heart and the great vessels.¹

Pathology—The etiological agent producing acute compression of the heart is always a fluid—either a liquid or a gas. Hemorrhage into the pericardial or mediastinal spaces is the most common cause of acute compression. It occurs when any of the mediastinal structures rupture or when they are penetrated as by a stab wound. Hemorrhage into the pericardial cavity may occur in scurvy and in the hemorrhagic diatheses. Tumors of the heart although rare have a tendency to bleed. The heart is acutely compressed when pus collects in the pericardial cavity. It may be compressed by an exudate or by a sterile effusion. Infections of a gas-forming nature in the pericardial and mediastinal spaces may produce compression. Air escaping from the lungs or trachea may produce pressure on the heart and the great vessels.

Compression of the heart produced by fluid may change from the acute to the chronic form. If the fluid

is in the pericardial cavity the pericardium stretches in response to the long-continued tension. The fluid may be walled off and localized either inside or outside the pericardium. Rheumatic fever and tuberculosis are most commonly associated with the formation of fluid but any pyogenic organism may be present. After a time a less virulent infection may spontaneously become quiescent, and the fluid may disappear. Residual signs of such an infection consist of adhesions and scar tissues. Bands or sheets of scar tissue gradually increase in density and like scars anywhere in the body undergo contracture. Such a scar may compress the entire heart or it may produce local compression.

Fig. 497.—The heart is compressed by fluid in the pericardial cavity. It is smaller than normal. Note the collapse of the intrapericardial segments of the venae cavae and the right auricle. The venous channels outside the pericardium are distended.

over the venae cavae, right auricle, right ventricle, left ventricle or pulmonary artery (Fig. 500).² Calcium may be deposited in the scar. Curiously enough the adhesions and scars following rheumatic fever do not produce compression of the heart.

The compressed heart is a small, shrunken organ. It cannot dilate. It cannot undergo hypertrophy. It receives a subnormal quota of blood and it performs a subnormal quota of work. It can do nothing about this reduction in work load. It receives and it pumps out whatever blood is delivered to it. As the work load of the heart is reduced, the cardiac muscle undergoes atrophy. It undergoes disuse atrophy in exactly the same way as does any other muscle in the body when it is not allowed to perform its full normal function. After compression has been relieved, some time is required for the cardiac muscle to regain its normal

stretch. Similarly the liver is not enlarged. As the flow of blood into the heart is reduced the output obviously is reduced by the same amount. The pulse weakens and signs of arterial failure appear. The patient at first shows anxiety and later unconsciousness from cerebral anoxemia. The skin becomes pale and cool. The heart is quiet. Pre-

it can be demonstrated roentgenographically. Pulsus paradoxus is present.

The chronic compression triad consists of (1) ascites, (2) a high venous pressure and (3) a small quiet heart (Fig 500 C). As ascites is one of the most conspicuous features in the severe form of compression. One patient calculated that he had had almost a

Fig 500.—Cardiac compression triad. For comparison normal (A), acute (B) and chronic (C). The acute compression is produced by fluid in the pericardial cavity. Note collapse of the venous gateway and distention of the veins outside the pericardium. The ventricles are shrunken a little heart *per se* is smaller than normal. The parietal pericardium has not had time to dilate nor has there been sufficient time for the liver to enlarge and for ascites to form. In the illustration for chronic compression of the heart the compression is produced by scar tissue. The heart is a small shrunken organ in contrast to normal. Cardiac distention. The veins dilate in response to the high venous pressure. The liver and spleen enlarge and ascites develops.

cordial pulsation is reduced or absent. The cardiac sounds are distant and faint. The area of cardiopericardial dullness is increased but in acute conditions the increase in size is slight and it is not worth delaying an urgent operation to obtain a roentgenogram. In a less acute condition the pericardium has time to stretch and the amount of fluid around the heart increases so that

ton of fluid removed from his abdomen over a period of four or five years. The ascitic fluid is a sterile straw-colored transudate. The venous pressure can rise to 42 cm of water. The walls of the veins stretch and become tortuous standing out like goose quills. The smaller veins also are distended and cyanosis is present. The liver and spleen en-

large and sometimes are covered by a layer of fibrous tissue and exudate. The cardiac sounds are distant and faint. The heart itself becomes a small shrunken organ. It is generally taught that the heart enlarges and undergoes hypertrophy in this condition. This is a fallacy. The compression agent makes it impossible for the heart to dilate or to undergo hypertrophy. While the heart is small the fluid or the scar compressing it

pulse pressure is narrowed and usually measures 20 mm Hg. The systolic pressure is about 100 mm Hg. The pulse is paradoxical.

Purulent Pericarditis—As a rule the diagnosis is established by the presence of fever together with signs of acute and chronic compression of the heart. The roentgenogram shows evidence of fluid in the pericardial cavity. Purulent pericarditis

Fig. 501.—Steps in the resection of a compression scar: *a*, a transverse incision on the fourth and fifth costal cartilages removed, the internal mammary vessels ligated, the mediastinum opened and the pleural sinus dissected in the left thorax in the compression scar which has two layers, the epicardial surface being shown; *c*, resection of scar from the heart; *d*, the pericardial muscle is replaced and closure is being started.

may give a large area of percussion dullness or a large roentgenographic shadow. It may or may not be fixed in position. Fixation of the heart by extrapericardial adhesions is of no significance with regard to either diagnosis or treatment. The electrocardiogram shows slurring and low voltage. Dyspnea on exertion, malnutrition, weakness, hydrothorax and subcutaneous edema are other manifestations of chronic compression. The

should be suspected in a patient who has an infection such as pneumonia or osteomyelitis and who is not improving satisfactorily. The diagnosis is confirmed by aspiration of pus from the pericardial cavity. If the pus is tuberculous repeated aspiration is required. In cases of non-tuberculous infection pericardiostomy is the only method of treatment. The operation consists of removal of the fifth left costal cartilage and suture of

the pericardium to the skin. A more extensive operation is not necessary. Irrigation with Dakin's solution or any strong antiseptic is contraindicated because such solutions erode the surface capillaries, resulting in the formation of scar tissue.³

Compression Scars.⁴—Chronic compression due to the contracture of scar tissue is designated by a confusing nomenclature, which includes such terms as adhesive pericarditis, mediastinopericarditis, Pick's disease, Concato's disease and polyserositis. Adhesions play absolutely no part in this disease. The diagnosis can be made with great simplicity and accuracy. The treat-

ADHESIONS TO THE HEART; ANGULATION AND TORSION OF THE HEART

It is generally believed that adhesions disturb the action of the heart and that they can produce dilatation, hypertrophy and failure.⁵ The relationship between adhesions, on one hand, and dilatation, hypertrophy and failure of the heart, on the other hand, has been generally considered as one of cause and effect. On the assumption that the heart wastes energy in pulling on the chest wall through adhesions, attempts have been made to correct this condition by operation. There are two possible ways of obtaining correction. One is to sever the central end of the

Fig. 502.—a and b, Chronic cardiac compression due to generalized epicardial and pericardial scar. Note the ascites and anxious expression. A bedridden cardiac invalid. c and d, Six years later, cured.

ment is surgical (Fig. 501). The scar is resected from the anterior and lateral aspects of the heart. The left side is resected before the right side. If the pulmonary artery or the venae cavae are compressed, these structures should be freed. The operation should be done after the patient becomes afebrile, sometimes months of rest in bed being necessary. In certain cases of tuberculous scar formation the waterlogging is so pronounced and rapid that resection must be done even though the infection in the scar shows activity. The results of the operation are excellent. Complete and permanent cure can be obtained (Fig. 502).

adhesions, i.e., the cardiac end. The other is to relax the particular part of the chest wall that is pulled on by removing the bony framework, ribs and sternum from that region. The first alternative was not utilized, but in 1902 the second idea was applied, and the Brauer operation came into use, being incorrectly called cardiolysis.⁶ The patients selected for the operation were those who had heart disease and adhesions and who showed various stages of dilatation, hypertrophy and failure of the heart. Most of them had rheumatic heart disease with a precordial heave, retraction of the chest wall and Broadbent's sign. Reasonable as it ap-

pears this theory has not met with satisfactory laboratory support. Also a critical analysis of the autopsy material of human hearts with adhesions does not support the idea that adhesions lead to dilatation, hypertrophy and failure of the heart. It can also be stated that a critical analysis of the results obtained by this operation shows that the operation is not clearly and definitely beneficial.

Adhesions can produce angulation and torsion of the heart. These displacements can produce symptoms by interfering with cardiac filling. Attacks of tachycardia and syncope may appear. Section of the adhesions, paralysis of the diaphragm and thoroplasty give beneficial results. Such cases of dislocation of the heart require treatment by operation. Disturbances of the circulation produced by angulation and torsion of the heart are not to be confused with the energy loss theory of pulling on adhesions.

DECOMPRESSION FOR CARDIAC HYPERTROPHY

The heart occupies practically all the space between the vertebrae and the sternum. On the assumption that this space is inadequate for the heart after it has undergone dilatation and hypertrophy, Morrison¹ in 1908 proposed an operation which might be called a decompression for such a large heart without adhesions. The operation consists of the removal of precordial ribs, cartilages and sternum. In young patients the precordium will bulge forward freely to accommodate an enlarged heart, but later on when the chest wall becomes less pliable this forward bulge does not occur. It is difficult to say how much benefit this operation gives to a dilated hypertrophic heart.

TRAUMA

Penetrating Wounds of the Heart and Intrapericardial Segments of the Great Vessels²—These are stab wounds or gun shot wounds. The wound of entrance is usually over the precordium but it may be elsewhere—in the neck, abdomen, buttock or esophagus. It may bleed and suck in air. Signs of acute compression establish the diagnosis. The escape of blood into the pericardial cavity may be rapid or slow. The wound may enter the myocardium at an

acute angle, in this event there may be little or no hemorrhage. Such a wound may recover spontaneously. Most wounds of the heart and intrapericardial segments of the aorta, pulmonary artery and venae cavae require urgent operation. The method of handling a ventricular wound is illustrated in figure 503. Ventricular muscle should never be taken in hemostats. The margin of an auricular wound, however, should be grasped in hemostats. The two margins of the auricular wound are brought together in the hemostats and the bleeding immediately ceases. Sutures are then placed and the clamps are removed. Bleeding from an auricle cannot be stopped by placing a finger on the wound. A large penetrating wound of the ventricle is rapidly fatal. If the blood escapes freely from the pericardial cavity exsanguination takes place. If the blood does not escape, compression rapidly develops.

A foreign body in the pericardial cavity or in the myocardium should be removed as soon as is feasible after the accident. If the patient is seen late the foreign body should be removed if possible because of the danger of cardiac rupture or the development of an embolus if the foreign body should work its way into the cavity of the heart. Sometimes the foreign body is securely fixed by scar tissue so that it cannot migrate. Exploration is advisable.

Non Penetrating Wounds, Contusions of the Heart²—Overlooked clinically and neglected surgically, the contusion is the most common form of cardiac trauma. The steering wheel injury is the classic and most common method of infliction (Fig. 504). Any severe blow over the precordium may produce contusion of the heart. The ribs and sternum need not be broken. A forceful localized impact over the precordium like the blow from a golf ball may produce contusion of the heart.

The signs and symptoms vary greatly. In most cases contusion of the heart produces no serious symptoms and is not recognized. Weakness is the most important symptom. It may appear immediately after the injury or it may not appear for several days. Usually weakness will disappear in a few minutes, hours, days or weeks, but occasionally it is a permanent symptom. A fall in blood

pressure occurs but as a rule this is transient and lasts but a few minutes. Pain is usually present. It is precordial and may go down the arm, as does anginal pain. Tachycardia is the rule and persists for minutes, days or years. Auricular fibrillation occurred in one of my patients, was permanent and did not respond to drugs. Brachycardia is rare. Electrocardiographic changes usually but not always occur. Changes in the T and deep Q waves are found. The tracings should be repeated daily in cases in which contusion is suspected. The alterations from normal usually, but not always, appear early and disappear within a few months. The changes in the electrocardiogram are to be differentiated from those occurring with

the purpose of preventing rupture or the formation of an aneurysm of the heart.

After the diagnosis of contusion of the heart has been made, the patient is kept at complete rest. If the condition is serious he is moved to the operating room for observation so that operation can be carried out immediately when definite indications appear. Morphine is administered. Quinidine is used to prevent ventricular fibrillation and to slow the rate. If rupture occurs, operation is indicated. If rupture does not occur, the patient is treated as though he had coronary thrombosis. He is kept in bed six weeks. It has been found that if the patient survives the first nine hours, his chances of surviving the first week are better than his chances of

Fig 503—Method of suturing a wound of the ventricle. A suture is placed in the apex so that the heart can be steadied and the finger can be held on the wound. Control sutures are crossed, the finger being removed, and the wound is sutured. The finger should not be inserted into the wound.

coronary thrombosis. Dyspnea on exertion and cyanosis are other symptoms.

Recovery is the rule. Death is the exception. It is amazing the amount of trauma that the heart can tolerate. Death may occur from ventricular standstill, from ventricular fibrillation or from cardiac rupture. Cardiac rupture is amenable to surgical intervention. A rupture of the auricle or ventricle can be sutured, although this operation has never been performed up to the present time in a case of non-penetrating injury. The patient should be continuously watched for signs of acute compression so that the operation can be performed before the heart permanently stops. I have described the method of applying free graft of pericardium or fascia lata to reinforce the contusion for

surviving the second week. Delaying hemorrhage may occur, and when it does, the treatment is operative. Pericardial effusion may appear and can be aspirated. Up to the present, surgical aid has been given to only two patients, one was treated by Mansell Moullin for the removal of bloody fluid from the pericardium and the other patient I operated on for ventricular fibrillation, which occurred as a terminal development. This patient had a mural thrombus in each ventricle.

Other forms of non-penetrating trauma to the heart occur. The heart may tear away from the aorta when the body falls from a high building. Compression of the legs and abdomen may drive the blood forcibly into the heart and rupture the right auricle. This

occurs in cave-in accidents Straining may rupture an auricle Indeed an auricle can rupture spontaneously Direct trauma to the chest may rupture the heart, any of the valves or a papillary muscle I saw one patient whose ventricles were strangulated through an opening in the parietal pericardium Some of these conditions can be treated by operation

Certain injuries to the upper portion of the abdomen such as those produced when a wheel passes over the body or when a horse rolls on the body result in rupture of the diaphragm and circulatory shock In these cases the shock has always been ascribed to rupture of the diaphragm but this

of movement disappears Each of these means death unless a coordinated contraction is restored to the heart In the vast majority of cases attempts at restoration are futile A myocardium poisoned by bacterial toxins or weakened by chronic disease cannot be made to function but a patient whose heart stops suddenly sometimes can be saved for instance a patient whose heart stops suddenly in the operating room as a result of anesthesia hemorrhage, respiratory paralysis, status lymphaticus electrocution from cauterizing vagus inhibition pneumothorax asphyxia or cardiac trauma

The first requirement in restoration of the heart beat is aeration of the lungs Success

Fig 301—The steering wheel accident an injury that will become a classic type always to be associated with contusion of the heart *

is a fallacious idea Tearing of the diaphragm does not produce circulatory shock The cause of the shock is the accompanying contusion of the heart The presence of cardiac contusion should be taken into consideration in deciding on the treatment to be given the diaphragmatic rupture Ventricular fibrillation is a threat to an early planned operation on the diaphragm

RESTORATION OF THE HEART BEAT

When the pumping action of the heart ceases and the arterial pressure disappears the ventricles either come to a complete standstill or go into incoordinated fibrillary twitchings for a while before every vestige

is impossible if the myocardium is evanescence Also the brain cannot tolerate anoxemia Aeration of the lungs is carried out either by forcing air and oxygen into an intratracheal tube or by mechanical compression of the chest Intratracheal insufflation is more effective and should be used whenever possible The patient must be kept warm

Ventricular Standstill—One cubic centimeter of 1 to 1,000 solution of epinephrine diluted with a few cubic centimeters of saline solution is injected into the left ventricle or cardiac muscle through the chest wall Massage is carried out through the chest wall If the heart does not begin to

* Beck J.A.M.A. 104

pulsate almost immediately, the chest is opened and the heart is directly massaged forty to fifty times per minute. Aeration through an intratracheal tube is being given at the same time. If the heart does not start, a similar quantity of epinephrine is dripped on the surface of the heart or is injected into the right ventricular cavity. Massage is continued. Too much epinephrine will throw the ventricles into fibrillation. Manual massage should be continued because it can keep all the tissues viable and the beat can be restored if the muscle has not been irreparably damaged.

Ventricular Fibrillation.^{10 11}—If the ventricles fibrillate, restoration of the coordinated beat is impossible until the fibrillary

will send the ventricles into fibrillation, but it is difficult to cause fibrillation after procaine or metycaine has been used. It is needless to say that perfect aeration of the lungs is given throughout the entire procedure. The human heart was defibrillated for the first time on Dec. 7, 1938.

TUMORS OF THE HEART AND PERICARDIUM

The heart, like other organs in the body, may be the seat of tumor formation, but this occurs rarely. Most of these tumors are metastatic, but a few are benign and operable. In one of our cases an intrapericardial dermoid produced pressure upon the right side of the heart, and it was completely and

Fig 505—Benign tumor of the left ventricular wall successfully removed at operation

movements disappear. This is accomplished by the use of procaine or metycaine on the heart. Two cubic centimeters of 5 per cent solution of procaine is dripped on the surface of the heart or injected into the right ventricular cavity. Massage is carried out continuously to maintain the circulation and to prevent dilatation of the heart. Success cannot be achieved if the heart is dilated. Two large electrodes are placed on the ventricles, and an alternating current of 1 to 15 amperes is sent through the heart for one-half to about two seconds. This sends all the fibers into contraction at the same time, and uniform relaxation follows. The heart is then at a standstill. Massage and epinephrine are used next. Too much epinephrine

successfully removed. Figure 505 shows a tumor in the wall of the left ventricle, which produced pain and dyspnea and which was completely and successfully removed. It had a calcified shell which contained putty-like material rich in fat. The patient was relieved of his symptoms.

PATENT DUCTUS ARTERIOSUS

The ductus arteriosus is an essential part of the circulation in fetal life. Its function is lost after birth, and normally the duct becomes obliterated. Obliteration is complete in 95 per cent of children at the age of twelve weeks and in 98.8 per cent at the age of one year.¹² Blood passes through this structure as long as it remains patent, be-

cause normally a differential pressure exists between the aorta and the pulmonary artery (Fig 506). As long as the pressure in the aorta is greater than the pressure in the pulmonary artery the flow is from the aorta into the pulmonary artery. Cyanosis there

ventricle.¹² It is obvious that this leak should affect the health of the patient. A small percentage of the patients tolerate the leak quite well but it is a constant drain upon the circulation. It is a factor in the development of endocarditis, endarteritis, heart fail

Fig 506—A Diagram of circulation showing the short circuit of blood through the patent ductus arteriosus. B Heart of a three day old child illustrating patent ductus arteriosus. (Holman and Beck.)

fore is not present. When the left ventricle fails the flow may be reversed and cyanosis may appear.

The ejection of blood from the aorta through the ductus into the pulmonary artery is forceful and produces a vibration or thrill similar to that of an arteriovenous

ure and pulmonary infections. These complications are the cause of death in almost 80 per cent of the cases.¹⁴

Diagnosis.—A correct diagnosis can be made in almost every case. Weakness, shortness of breath and fatigue on exertion are the usual symptoms. The patient may be un-

Fig 507—Phonocardiogram and electrocardiogram (lead 2) of a patient with patent ductus arteriosus. Note murmur during both systole and diastole also disappearance of the murmur after ligation of the ductus.

fistula. The alterations in the physiology of the circulation are precisely similar to those produced by an interventricular leak and consist of an increase in the circulating blood volume, a lowering of the diastolic arterial pressure and dilatation and hypertrophy of the heart, especially of the left

ventricle. Cyanosis is not present as long as the heart is compensated. The patient may be subject to frequent pulmonary infections.

The thrill and the murmur are the most important diagnostic aids. The thrill is produced by the leak and is felt in the second

or third intercostal space to the left of the sternum. The patient or the mother may be aware of a noise in the chest. The thrill may be continuous, with accentuation during either systole or diastole. The murmur is loud and machine-like and is systolic and diastolic (Fig. 507). Exercise may be necessary to bring out the diastolic component. The murmur is loudest in the region of the thrill and may be faintly heard over the apex. It may also be heard in the neck and between the scapulae. The systolic arterial pressure is normal, while the diastolic ar-

are are cut across, and the pleural and mediastinal cavities are opened. Mechanical respiration should be used during the operation.¹⁶ Figure 508 indicates the anatomical structures encountered in the operation.

Recently the operation has been applied to patients with bacterial endarteritis. One of these patients was cured of the blood stream infection after the operation.¹⁷ In the presence of endarteritis there is an extra hazard to the operation, consisting of a greater likelihood of tearing either the aorta or pulmonary artery or the duct

Fig. 508.—Patent ductus arteriosus. Inset shows the structure ligated with tape. Recurrent laryngeal, vagus and phrenic nerves are shown.

terial pressure is less than normal. The pulse pressure is increased. The heart may not be enlarged.

Treatment.—The treatment of this condition consists of ligation of the ductus whenever possible.¹⁸ In some cases the opening consists of a fistula between the aorta and the pulmonary artery, and closure of the fistula by a ligature is technically impossible. If the duct can be isolated without too much risk in the dissection, it should be ligated with tape. The approach is through an incision between the second and third ribs. The second and third costal cartilages

Cardiologists do not agree concerning the indications for operation in this condition, but it seems to me that there is little room for argument. The duct should be ligated in every condition if this can be safely done. With good mechanical respiration the hazard of the operation should be very slight.¹⁹

ESTABLISHMENT OF A NEW BLOOD SUPPLY TO THE HEART BY OPERATION

Anatomical and Experimental Considerations.—The circulation in the heart muscle can be altered by operative methods, and these alterations can protect the heart against the ravages of coronary artery

disease Protection against coronary artery occlusion can be given in two ways (1) by the establishment of an extracoronary vascular bed and (2) by the establishment of communications between the three major coronary arteries The extracoronary vascular bed is produced by grafting vascularized tissues upon the surface of the heart The tissues available for grafting are parietal pericardium mediastinal fat skeletal muscle from the chest wall and omentum brought up through an opening in the diaphragm Communications between the coronary arteries and the arteries of the grafts have been demonstrated by experiment¹⁸ This grafting operation is made possible because the heart has a free surface on which grafts can be placed The production of intercoronary communications has been demonstrated by experiment¹⁹ They can be produced by two methods one of these being occlusion of a coronary artery If one of the major arteries is occluded and if the animal survives the occlusion then the three major arteries become anastomosed A retrograde flow develops into the occluded artery from the other arteries and after a period of weeks or months a good blood flow is produced to that part of the myocardium that was supplied by the occluded vessel It is obvious that this stimulus to the development of intercoronary communications cannot be utilized as a therapeutic measure However nature does utilize it in the presence of coronary artery disease As coronary sclerosis develops in the human heart intercoronary communications develop and protect the heart against the disease In many instances the improved circulation is such that death is averted until two or more of the major vessels become occluded²⁰ Indirectly it can be shown that this stimulus can be utilized by operative methods There are two destructive factors which appear as a major coronary artery becomes occluded One of these is an increase in the irritability of the anoxic muscle so that the ventricles lose their coordinated rhythm and go into fibrillation This is fatal The other factor produced by occlusion is death of myocardium from lack of oxygen Muscle deprived of its blood supply is changed to scar tissue and this alteration is irreversible Both of these destructive factors can be held in abeyance by a relatively small amount of blood supplied to the occluded artery If the heart can survive the crisis produced by occlusion so that ventricular fibrillation does not appear and the myocardium does not die then reparation is possible The occlusive stimulus has time to express itself The circulation improves and these threatening factors disappear The coronary arteries are now joined together This relatively small amount of blood required to keep the muscle viable and to prevent fibrillation can be given to the occluded artery by operative methods¹⁹

The other method by which intercoronary communications can be produced is by means of inflammation This is a surgical method The inflammatory agent can be either chemical or physical A special study of this subject has been carried out²¹ and it has been found that calcium and magnesium silicate applied to the surface of the heart in small quantities produces the most favorable result Many chemical agents produce a severe reaction and are dangerous It has also been found that abrasion of the surface of the heart

without the use of chemical irritants or grafts opens up intercoronary channels¹⁹ Abrasion alone can reduce the mortality produced by coronary artery occlusion and it also can reduce or entirely prevent the formation of an infarct after a major coronary artery has been ligated

The presence of a common coronary bed affords protection to the heart in the presence of coronary arteriosclerosis Conversely, the absence of such communications makes the heart vulnerable to occlusions The communications between coronary arteries vary in different normal hearts In some they are practically absent in others communications are present but they are never very pronounced

The Beck Operation for Coronary Artery Disease—This operation was devised for the purpose of improving the circulation to the heart muscle Grafts were placed upon the heart the surface of the heart was abraded and powdered beef bone was placed upon the abraded surface to produce an inflammatory reaction The tissues used for grafting purposes consisted of parietal pericardium mediastinal fat and skeletal muscle from the chest wall This operation was performed on a group of thirty patients²² The results in general have been favorable and in some of the cases have been almost incredibly beneficial Although all of the patients were totally incapacitated before operation many of them were able to return to work after operation

Certain premises should be borne in mind in reference to this operation The operation does not eradicate the disease and complete cure is not to be expected One must think in terms of improvement rather than of cure One must accept the conclusion that a scar in the myocardium remains a scar it can not be changed back to myocardium It is to be expected also that certain patients may not appear to be helped by the operation because the destructive process of the disease may be more rapid than the reconstructive process following the operation Also in one type of disease the benefit from the operation may not be very great This is the type in which all the major coronary arteries undergo a similar degree of occlusion In this type of disease the anoxemia of the heart muscle is generalized and the requirement for cure consists of an outside blood supply of large proportions The blood vessels in the grafts are large enough to be easily seen in cleared specimens Whether they can become a complete and adequate substitution for the coronary arteries remains to be determined but this is an almost unreasonable expectation It is implied that the greatest benefit is to be expected in those cases in which localized anoxemia is present

After doing the operation on a study group of thirty patients it was decided not to do it on a clinical patients until more data were obtained Six years have elapsed since the last operation was done Recently we have taken up the operation again it will be tested and the results measured If these preliminary tests are satisfactory the operation will be ready for application

We used omentum in some of our early experiments carried out in 1932 and we were able to demonstrate anastomoses in these grafts We have not used this procedure on patients but O'Shaughnessy has done so

with beneficial results.²³ We have not used it on patients because of the danger of opening the diaphragm with resulting complications involving the abdominal viscera.²⁴

OTHER CARDIAC OPERATIONS

Angina pectoris has been treated by cervical sympathectomy, by injection of alcohol into the ganglia of the thoracic sympathetic system and by complete thyroidectomy. Cervical sympathectomy has not given encouraging results. Total thyroidectomy has been recommended, but a final statement regarding it cannot be given at present.²⁵ These procedures treat the symptom of pain rather than the disease.

Several attempts have been carried out to relieve mitral stenosis by incision of the stenosed ring or by removal of a segment of the valve.²⁶ Stenoses of other valves (aortic and pulmonic) have been operated on; these operations on cardiac valves are still in the experimental stage.

XXIV. THE MEDIASTINUM, INCLUDING THE ESOPHAGUS

MEDIASTINAL EMPHYSEMA

Tension emphysema (presence of air) of the mediastinum is particularly important because it threatens life and demands emergency treatment. As the pressure rises the great veins are collapsed and the return of blood to the right heart is so compromised that death from circulatory failure may ensue in a few minutes. The superficial veins become engorged, the pulse becomes rapid and soft and the blood pressure falls steadily. Sauerbruch believes that severe emphysema originating in the chest wall may invade the mediastinum and produce the same effects.

Treatment—Most cases of traumatic emphysema require no treatment. The opening through which the air is escaping closes spontaneously and the air in the tissues is gradually absorbed. In the mouth or pharynx either suture or packing of the wound is a feasible and logical procedure. If the injury has been to the lung a roentgenogram should be taken to determine the nature of the injury and the presence or absence of pneumothorax and of air in the mediastinum. If ribs have been broken or if the chest wall has been penetrated and pneumothorax exists there is reason to believe that the air is escaping through the parietal pleura. In such cases a tight thoracic swathe may prevent further leakage and aspiration of the pleural cavity either at intervals or by continuous suction through a needle is indicated both to relieve a rising intrapleural pressure and to prevent further spread of the emphysema. Because the collapse of the lung favors the closure and healing of the wound aspiration should be done guardedly and only on the indications of severe emphysema or increasing dyspnea. Expectant treatment is often the best.

If there is reason to believe that there is involvement of the mediastinum the pulse rate and blood pressure must be carefully watched. A rising and weakening pulse and a falling blood pressure are indications for immediate surgical intervention. This is sim-

ple and safe aiming merely at relieving the pressure by allowing the air to escape through incisions made close to the site of egress from the mediastinum. The supraclavicular fossae posterior to the sternomastoids and the suprasternal notch are the locations of choice. The incisions should be carried through the platysma and the tissues spread by blunt dissection to the level of the great vessels. Air will escape rapidly at first and that which is at a distance from the incisions can be massaged toward them. Constant or intermittent suction applied by means of a vacuum cup attached to a suction apparatus is often necessary. The wounds will permit the exit of air for from twelve to twenty-four hours. The tissue spaces then become blocked by exudate and if the symptoms recur new incisions must be made.

JEROME R. HEAD

MEDIASTINITIS

Definition—Mediastinitis is an inflammation occurring within the middle space of the chest limited by the spine behind, the sternum in front and the pleura on either side.

Anatomy—The mediastinum is a potential space of loose areolar tissue and while it is divided into anterior, middle, posterior and inferior divisions these are arbitrary and are not separated by well defined fascial planes or other structures. Hence there are no strict anatomical limitations of infection in the mediastinum. However fascial planes may direct infection from the neck to the anterior or the posterior mediastinum. The pretracheal space and the retrovisceral space are the major pathways for infection from the neck to the thorax.

Etiology—There are three main routes by which infection reaches the mediastinum: via (1) the lymphatics and (2) the fascial planes from the neck or (3) by direct extension from structures within the mediastinum. There is an abundant supply of lymphatics with drainage from the lungs

neck chest diaphragm and abdomen and suppurative lymphadenitis might be expected to be the most common cause of mediastinitis whereas it is the least common. The fascial planes of the neck extend into the mediastinum the prevertebral pretracheal and middle cervical fasciae being continuous with the fascial layers in the mediastinum. Pus from a retropharyngeal abscess or cervical adenitis if allowed to progress may readily extend into the mediastinum. Operations in the neck as for esophageal diverticulum have resulted in mediastinitis. More benign conditions such as acute pharyngitis or laryngitis may give rise to mediastinitis usually by way of the lymphatics. The esophagus trachea and bronchi all potentially infected structures pass through the mediastinum and infection from these by direct extension is relatively common. Perforation of these structures by instruments foreign bodies ulceration or tumors is not uncommon. During World War I autopsies on patients with pneumonia and empyema showed 12 per cent with mediastinitis. Osteomyelitis of the surrounding structures—the sternum ribs or vertebrae—also may result in mediastinitis.

Pathology—The most common infecting organism is the streptococcus although a great variety of organisms have been described. For clinical purposes two forms of infection may be described (1) local suppurative or mediastinal abscess and (2) the diffuse form termed phlegmonous mediastinitis. The former more commonly follows the direct extension or perforation of pus into the mediastinum while the phlegmonous variety is more commonly of lymphatic origin. Owing to the loose areolar tissue of the mediastinum there is usually no encapsulation as in abscesses elsewhere and an abscess beginning in the posterior mediastinum may extend through the middle to the anterior mediastinum or vice versa. Phlegmonous (non suppurative) mediastinitis frequently is accompanied by bilateral suppurative pleuritis especially in the posterior mediastinum. It is likely that acute mediastinal lymphadenitis is more frequent than is commonly recognized.

Diagnosis—It has been pointed out that the pathologic picture of mediastinitis is varied consequently the clinical manifesta-

tions are seldom alike. The signs and symptoms usually described—chills fever prostration severe toxemia and interference with the circulation—are the exception rather than the rule. The fulminating type of the disease may present this picture but more often the disease is slowly progressive and not infrequently with remission. The signs and symptoms must be interpreted in the light of possible involvement of any of the structures passing through the mediastinum such as increased venous pressure respiratory embarrassment dysphagia obstruction of the thoracic duct or involvement of the sympathetic vagus or phrenic nerves. The diagnosis of an early case of mediastinitis is difficult and may be arrived at only by exclusion of primary pulmonary or cardiac disease. The patient may present symptoms suggesting pneumonia but roentgenograms will fail to reveal evidence of such involvement and are usually likewise negative for mediastinal involvement. However later they may reveal a widening of the mediastinum or a globular shadow. Latent films particularly of the superior mediastinum may be helpful and a swallow of barium to outline the esophagus is extremely useful. Occasionally a fluid level may be demonstrated. It should be emphasized that posterior mediastinitis is frequently accompanied by pleural effusion which may be bilateral. The possibility of a foreign body in the esophagus or trachea should also be kept in mind.

Treatment—The treatment of mediastinitis should be directed at the cause whenever this is recognized such as a foreign body in the esophagus or a deep cervical abscess. These two factors alone account for more than half the cases of mediastinitis. When there is localized pus in the mediastinum drainage is clearly indicated. However there is another group of cases in which the clinical course signs and symptoms indicate pus in the mediastinum which cannot be demonstrated but in which an exploratory operation is indicated. While there are undoubtedly instances of mediastinitis with spontaneous recovery there are many more in which death ensues because of failure to drain pus which cannot be demonstrated without operation.

The superior mediastinum down to the

level of the third thoracic vertebra may be approached through the neck. Therefore, in cases of actual or threatening mediastinitis due to esophageal perforation or infections bilateral exposure of the cervical portion of the esophagus for drainage and packing is indicated. The posterior mediastinum should be approached by resection of the posterior portion of three or four ribs and careful separation of the pleura from the bodies of the vertebrae. Every effort should be made to keep the pleura intact but even if the pleura is opened it is less dangerous than undrained mediastinitis. When pus is in the anterior mediastinum a substernal or parasternal approach may be used. The operative mortality is not as high as is frequently assumed. From one half to two thirds of the patients operated on survive whereas the reverse is true when an operation is not performed.

COLONEL ASHLEY W. OUCHTERLON

TUMORS AND CYSTS OF THE MEDIASTINUM DERMOID CYSTS

In the literature the term dermoid cyst has come to include the epidermoid and dermoid cysts as well as the histologically more complicated teratomas of the mediastinum although from the standpoint of their pathology, symptomatology and treatment the e types of tumors may differ widely.

Incidence.—Although uncommon intra thoracic dermoid cysts are not nearly so rare as was formerly supposed about 220 cases having been reported.

Etiology and Pathology.—These tumors are congenital and are thought to arise from ectodermal rests or misplacements of bronchiogenic cells drawn into the thorax by the descent of the diaphragm and the heart. They are most frequently encountered in the superior and anterior mediastinum in front of the great vessels and often lying in contact with the pericardium. They may occasionally be associated with other congenital anomalies such as spina bifida or exstrophy of the bladder. They are of slow growth and usually remain quiescent for a number of years rarely giving rise to symptoms before adolescence. Trauma or intra thoracic disease may serve to call attention

to their presence or may actually cause a more rapid growth.

Symptoms.—Rarely appearing before the age of puberty dyspnea, pain and cough are the common symptoms. The dyspnea appears at first only on exertion but becomes progressively more troublesome and late in the course may be paroxysmal in nature. The pain may be dull or acute and is sometimes referred to the shoulder or neck or down the arm. Cough may begin as a symptom of respiratory infection and may fail to subside as the infection clears or it may appear spontaneously. Sputum is usually scanty, and confined to mucus occasionally blood streaked unless the cyst ruptures into a bronchus in which case the cyst content

Fig. 509.—Dermoid cyst of the mediastinum

consisting of hair and grumous material containing desquamated epithelial cells may be expectorated. Symptoms of vascular and neural compression may also be present and pleural effusion occasionally is seen. Fever may occur but is of low grade unless complicating infection is present.

Clinical Course.—The cases of intra thoracic dermoid cysts have been divided into three groups on the basis of their clinical course. Usually the onset is insidious followed by the gradual progression of symptoms. Less frequently a very stormy course may follow an insidious onset the severe symptoms being associated with infection. More rarely still a stormy onset may be followed by alternating exacerbation and remission of symptoms.

Unless treatment is instituted the condition usually ends fatally. Thus in Aueron

seau's series excluding 10 cases in which the cyst was discovered at necropsy there were 34 deaths in 34 untreated cases. However patients may live for a number of years after the onset of symptoms. 7 patients in Morris' series died in less than one year, 10 died in from one to five years and 12 lived more than five years after the first symptoms referable to the condition.

Physical Signs—The physical signs vary considerably according to the size of the tumor and the presence or absence of complications such as infection, rupture of the cyst, etc. On the whole signs of mediastinal compression are not common with dermoid cysts but with larger cysts the mediastinal structures may be dislocated. Occasionally the cyst may rupture externally giving rise to a sinus from which hair and other elements from the cyst may be discharged. Lagging or bulging of the thoracic wall may be evident on inspection and percussion may reveal an area of dullness which may be taken for encapsulated fluid. On auscultation breath sounds may be absent over the dull area while rales or modified breath sounds may be heard elsewhere owing to bronchial compression.

In the x-ray picture a circular or oval shadow with a well defined margin is seen its lateral border extending out into the pulmonary field but the medial border is always connected with the mediastinum. Lateral x-ray pictures may be useful in demonstrating the location of the cyst in the anterior mediastinum. The wall of the cyst may cast a distinct shadow particularly if calcification is present. If the cyst has ruptured into a bronchus it may collapse or a fluid level may be demonstrable within the cyst. Pleural effusion may obscure the shadow of the cyst which will appear only after thoracentesis.

Treatment—In the case of a cyst which is discovered accidentally in the course of a routine examination of the chest and in the absence of any symptoms the advisability of surgical intervention may be open to question but when symptoms and particularly those of pressure are evident treatment should not be delayed. Complete extirpation is the treatment of choice as in 76 cases this was followed by cure in 89.3 per cent with a 10.7 per cent mortality. In simple drainage of the cyst the mortality was

26.5 per cent and the cures only 15 per cent while with partial resection the mortality was 16.6 per cent and the cures 41 per cent.

CILATED EPITHELIAL CYSTS

Simple cysts lined with ciliated epithelium have been found in the mediastinum and their origin in the thymus or in aberrant rests from the pharyngeal ectoderm in connection with the development of the esophagus or air passages has been suggested. Such cysts may attain considerable size and commonly arise near the tracheal bifurcation or close to the lower portion of the esophagus.

CYSTIC LYMPHANGIOMA

A few reports of cystic lymphangioma are to be found in the literature. These have been found for the most part near the tracheal bifurcation or in connection with the pericardium. Operation was attempted in Michaelis' case because of severe pressure symptoms but removal of the cyst was found to be impossible and the patient died.

ECHINOCOCCUS CYSTS

Echinococcus cysts of the mediastinum are distinctly rare. Hare reported 8 and Hoffman 4 cases. Rose's patient was successfully operated on and cured after excision of the lining membrane of the cyst and drainage.

TUMORS OF THE CONNECTIVE TISSUE

These include the fibromas, lipomas, leiomyomas, xanthomas, chondromas, chondromyxomas, ganglioneuromas and neurofibromas.

Fibroma—Pure fibromas are rarely found in the mediastinum in most of the reported cases these tumors contained other connective tissue elements. In size they vary considerably and may become as large as a child's head. They are frequently adherent to the mediastinal structures or to the pleura or diaphragm. Like fibromas elsewhere they vary in consistency and are well encapsulated.

The symptoms of fibroma are those common to other benign tumors and may be present in varying degrees over a considerable number of months or even years. Pain in the chest, cough and dyspnea have been outstanding while hoarseness, pain and

swelling of the arm and dysphagia also have been noted.

Physical signs do not distinguish these from other mediastinal tumors. Localized dullness and signs of bronchial vascular or neural compression have been the common findings. The x ray picture shows a clearly defined and circumscribed shadow extending into the pulmonary fields and blending with that of the mediastinum or heart.

Diagnosis—Positive diagnosis has been possible only at operation or necropsy. The commoner benign tumors of the mediastinum such as dermoids, lipomas or ganglioneuromas have usually been suspected.

The *prognosis* is excellent if operation is possible. In a group of 32 cases reported in the literature 18 of the patients who were not operated on died while of the 14 subjected to operation 13 recovered after removal of the tumor and 1 died.

Neurofibroma—The posterior mediastinum is sometimes the seat of a neurofibroma arising from the sheath of a thoracic spinal nerve. The clinical picture is that of the ordinary fibroma but pain is an early and prominent symptom and tends to radiate along the course of the intercostal nerves. When the tumor arises in the intervertebral foramen it may extend into the spinal canal as well as into the thorax giving rise to a so-called hour glass tumor. Such a tumor gives evidence of compression of the spinal cord and requires laminectomy as well as the racotomy for adequate removal. In the case of a neurofibroma arising from an intercostal nerve some erosion of the rib immediately above and below the site of origin of the tumor may be evident in the x ray picture which otherwise simulates closely that of ordinary fibroma.

The treatment is surgical and the outlook good provided the operation is undertaken before the tumor has become too large or has undergone malignant change. Of 21 reported cases 4 were found at autopsy. Operation was performed in 17 cases with 5 deaths (29.4 per cent) and 12 recoveries (70.6 per cent).

Ganglioneuroma—Although in some of the cases of ganglioneuroma the tumors have been located outside the chest—in the abdomen or neck, about 70 have been found in the posterior mediastinum springing from the thoracic sympathetic ganglionic

chain. They vary considerably in size and may be 15 cm in diameter. They appear as firm lobulated tumors the cut surface of which is gray and glistening. Microscopically they are seen to be made up of reticular net work containing groups of multipolar ganglion cells.

The symptoms are those of an intrathoracic fibroma but when Horner's syndrome appears early or is the initial symptom the diagnosis of ganglioneuroma should always be seriously considered.

Since this type of tumor is insensitive to radiation it should be subjected to operation for it usually can be removed often this can be done extrapleurally.

Fig. 110.—Ganglioneuroma arising from the paravertebral ganglion chain. Operative removal was successful.

Lipoma—Lipoma of the mediastinum is rare only 42 such tumors involving the thorax having been reported in the literature. Of these 40 arose in or at least involved the mediastinum. These tumors may conveniently be divided into three groups: one group comprising about three fifths of the total number in which the tumor lies completely within the thorax; another group in which intrathoracic and extrathoracic portions of the tumor are connected by a narrow isthmus traversing a perforation in the thoracic wall; and a third group in which a mediastinal tumor extends upward into the neck.

These tumors grow slowly and may attain great size in one case (Leopold's) weighing 17½ pounds and are often slow in producing serious pressure symptoms.

While the presence in the x ray picture of

an intrathoracic shadow of clearly demarcated outline with its central portion denser than its periphery should make one suspicious of lipoma the diagnosis has seldom been made before operation or necropsy. When such a shadow is seen in the chest below an external tumor in the neck or presenting anteriorly and exhibiting the physical characteristics of lipomatous tissue the diagnosis is definitely suggested.

Treatment—Of the 13 patients in whom external tumors were present 12 were subjected to operation and 1 died untreated of mediastinal compression. Seven of the patients operated on were cured while 5 died. Of the 24 patients in whom the tumor was entirely intrathoracic 16 died untreated while of the 8 patients who were subjected to operation 5 recovered after removal of the tumor and 3 died.

Chondroma Chondromyxoma Chondromyxosarcoma—Primary cartilaginous tumors arising from the ribs and their cartilages from the sternum or from the vertebral column may project into the mediastinum. Of these tumors arising from the ribs and costal cartilages are by far the most common. They are not invasive unless malignant and indeed are usually well encapsulated and appear as circumscribed sharply demarcated often nodular tumors. They vary in size and may be as large as a child's head. Their consistency depends on whether the chief component is cartilage or the softer even semifluid myxomatous tissue. While many of these tumors appear grossly to be benign they are prone to undergo malignant change. Clinical and x-ray evidences of metastases in the lung are often present in the later stages of the disease.

Symptoms—Clinically these tumors are

more often seen in adults than in children. Pain is an early and often the only symptom its location character and severity being somewhat dependent on the site of the tumor. An external mass may be noted by the patient if the tumor involves the ribs and costal cartilages. Cough and dyspnea are of later onset and commonly increase in severity with the growth of the tumor. Symptoms of mediastinal compression suffusion of the face cyanosis vascular engorgement hoarseness or dysphagia or signs of pressure on the sympathetic trunk also may be present.

Physical signs may be meager at first later signs of mediastinal or bronchial compression and local bulging of the thorax appear. The roentgenogram shows a circumscribed shadow and its origin in the bony thorax may often be demonstrated.

Treatment—Surgical removal is the treatment of choice and the results in general are quite satisfactory. The operative mortality while decreasing is still fairly high and many of the patients have recurrences.

Xanthoma—In the literature there are references to 5 cases of mediastinal tumor diagnosed on pathologic examination as xanthomas. They are benign tumors and amenable to operative removal. The fact is significant that in one of the reported cases bloody pleural effusion was present.

TUMORS OF THE MEDIASTINAL LYMPH NODES

The mediastinal lymph nodes may be the site of origin of a variety of tumors as indicated in the following classification modified from Ewing and based on the anatomical components of the nodes and the tumors arising from them.

Origin	Anatomical Type	Clinical Type
1 Lymphocyte	Lymphocytoma	Simple lymphoma
2 Reticulum cells	Large round cell lymphoma or neoplasia	Lymphatic lymphoma
3 Endothelial cells	Endothelial hyperplasia	Lymphatic leukemia Pseudoleukemia Lymphosarcoma (small cell) Myeloid leukemia Malignant granuloma Hodgkin disease Large cell lymphosarcoma Endothelial hyperplasia of the cellular or other chronic lymph adenitis Endothelioma

Lymphosarcoma.—Lymphosarcoma has been the commonest type of mediastinal tumor in all large series in which careful pathologic studies have been made. In Ross' series of 60 cases, 41 were sarcomas, and of these 32 were lymphosarcomas.

Occurring most frequently between the ages of thirty and fifty and predominantly (in ratio of 2 to 1) in males, these tumors evidence no definite etiologic factors.

Symptoms.—The outstanding symptoms are pain, tumor or swelling and signs of mediastinal compression. The order in which the various symptoms appear may vary considerably, and any one may antedate the others. Cough, either dry or with meager expectoration, and dyspnea on exertion may be the initial symptoms. Hemoptysis is not uncommon, and low grade fever, usually under 100° F. in the absence of complications, is the rule.

The *physical signs* depend to a great degree on the size and location of the lymph nodes and when present are those of compression of various mediastinal organs. In addition, a swelling may be noted in the suprasternal fossae or at one side of the sternum. X-ray pictures show widening of the mediastinal shadow and particularly of the supracardiac shadow, of varying outline and character.

Pleural effusion occurs in about 50 per cent of the cases, and in some of these cases characteristic cells may be found in centrifuged sediment of fluid obtained by thoracentesis.

If an enlarged node can be removed for histologic examination, the diagnosis is established; otherwise it must be made largely by exclusion. Benign lesions are less common and slower growing, and they show little change after radiation; whereas cases of both lymphosarcoma and Hodgkin's disease may be much benefited by x-ray treatment.

The disease is uniformly fatal and pursues a rapid course, the average duration of life after the onset of symptoms being under one year. Death may result from complications such as pneumonia or from exhaustion, asphyxia or cardiac failure.

Treatment is palliative at best, although temporary regression of the process, with considerable relief of symptoms, may often

be brought about by intensive use of deep x-ray or radium therapy.

Hodgkin's Disease.—Hodgkin's disease is of importance surgically chiefly from the standpoint of differential diagnosis, since it may cause many symptoms which are also found in cases of other mediastinal tumors.

Fig 511—Lymphosarcoma of the mediastinal cervical and axillary nodes before treatment

Fig 512—Same case shown in figure 511, three months after intensive x-ray treatment showing marked reduction in the size of the mediastinal nodes

Although certain prodromal symptoms, such as itching or eczematous eruptions of the skin, may occur, enlargement of lymph nodes is by far the commonest initial symptom, having been noted in 52 of 72 cases (72 per cent) of Gower's series, and in 71 (80 per cent) of Longcope's 86 cases. Beginning usually in the cervical nodes, the disease may spread to the mediastinum or more rarely may be primary in the mediastinal nodes.

The enlarged mediastinal nodes may remain discrete or may fuse into a more or less solid mass encircling the trachea bronchi or great vessels. In addition the lungs pleura pericardium cardiac muscle or liver may be invaded. The spleen is enlarged in about 10 per cent of the cases.

Symptoms of mediastinal compression predominate when the nodes in this region are involved. Pain in the chest may be retrosternal or referred to the shoulder or down the arm. Cough may be a prominent symptom and dyspnea and cyanosis are usually observed. Signs of vascular compression or of pressure on nerve trunks may be encountered.

Diagnosis—While the clinical and x-ray pictures of progressive enlargement of the mediastinal nodes are quite characteristic the differential diagnosis of Hodgkin's disease and lymphosarcoma rests largely on the histologic findings in an excised node, even with this aid it may be extremely difficult at times. Fortunately however this differentiation is not entirely necessary from the therapeutic standpoint since both yield to a certain degree to x-ray or radium treatment. In both there is a great tendency to recurrence and while life may be prolonged for as long as several years cures are not effected.

Endothelioma—In rare cases the mediastinal nodes may be the seat of a primary endothelioma but more often these nodes are involved by secondary invasion of pleural endothelioma into the mediastinal structures. The differential diagnosis from other tumors of the mediastinal nodes can be made only after microscopic examination either of tissue or of the sediment of pleural effusion if it is present.

PRIMARY TUMORS OF THE THYMUS

The thymus may occasionally be the site of a benign tumor such as a cyst cystic lymphangioma lipoma or the very rare congenital myxoma but in nearly all cases the primary thymic tumor has been malignant. The neoplasm may originate either in the lymphoid or in the reticulum cells giving a histologic picture resembling on the one hand lymphosarcoma and on the other carcinoma. However because of the confusion which still exists as to the exact origin of the

different elements of the thymus recent writers have urged the inclusion of all primary malignant tumors of the thymus under the term thymoma.

About 100 such tumors are reported in the literature classified variously as lymphosarcoma carcinoma and sarcoma. Of these about 75 per cent have been diagnosed as lymphosarcoma.

The *symptoms* are those of progressive mediastinal compression and in addition pleural effusion fever loss of weight cachexia and anemia may be present. The tumor grows rapidly and causes death in a relatively short time. A number have been associated with myasthenia gravis (See section on Abnormalities of the Thymus).

Diagnosis—Except for the recognition of a mediastinal mass in the region of the thymus positive diagnosis can rarely be made ante mortem.

Treatment—The best results have followed intensive radiotherapy but its effects are palliative at best. In a few cases operation has been performed.

CARCINOMA OF THE MEDIASTINUM

Under this term is included a miscellaneous group of primary and secondary malignant tumors. A primary tumor arises from the reticulum cells of the thymus while a secondary tumor is the result of extension from a primary carcinoma of the lung trachea bronchus breast or esophagus or of metastases from a more distant focus.

Although distinctly less common a carcinoma cannot be differentiated from a sarcoma arising in the same structure. It often reaches considerable size filling the anterior mediastinum and subsequently surrounds the trachea bronchi nerves or esophagus and extends to the pericardium pleura and lung. Metastases may occur also in the pleura lung liver spleen kidney and other organs.

Symptoms—In general the symptoms are those of pressure on the various mediastinal organs and some writers have emphasized the comparative frequency with which these tumors are associated with early vascular engorgement and swelling and edema of the abdomen and extremities due to involvement of the azygos vein. Serous or bloody pleural effusion is fairly common.

The diagnosis of mediastinal tumor is usually not difficult but the diagnosis of carcinoma depends on the availability of superficial nodes for biopsy.

Involvement of the mediastinum from carcinoma of the breast by extension may occur and in certain cases an attempt at removal of the lesion with the overlying ribs and sternum may be feasible although fairly prompt recurrence usually takes place.

While carcinoma of the esophagus often involves the mediastinal nodes the occurrence of compression symptoms is rare.

WILLIAM DEWITT ANDRUS
GEORGE J. HEUER

THE ESOPHAGUS

Knowledge concerning diseases and functional disturbances of the esophagus has been developed slowly. This is due to the vagueness of symptoms early in the disease as well as to the inaccessibility of the esophagus. Usually some difficulty in swallowing first attracts the patient's attention but because in the beginning this does not seriously interfere with the intake of food he adjusts himself to the difficulty rather than consult his physician. As a result the underlying condition progresses until discomfort in the chest, pain, salivation, eructation, regurgitation of food or loss of weight alarm the patient sufficiently to make him seek medical advice.

On account of the deep position of the esophagus in the chest where it is inaccessible to palpation, ordinary means of physical examination fail. On clinical data alone the physician can usually only suspect an esophageal lesion. The symptom of dysphagia alone, however, should arouse suspicion and requires investigation with all known means.

Experience has shown that it is unwise to attempt blind instrumental manipulation. The cooperation of specialists is urgently indicated to establish the diagnosis positively.

The simplest examination is a roentgen examination with a contrast medium. By means of roentgenography one may study the position, size and shape of the esophagus as well as variations from the normal. Fluoroscopic examination permits a study of the function of the organ under normal

and abnormal conditions and cinefluorography allows permanent records to be made of such function. By these means a correct diagnosis can frequently be made.

In case the roentgen findings are inconclusive consultation with a peroral endoscopist is indicated for the purpose of performing esophagoscopy. The addition of the esophagoscope to the armamentarium not only has aided in the diagnosis of esophageal lesions but has permitted local treatment and the taking of biopsy specimens.

The esophagus is subject to affections similar to those found in other organs of the body. The age of the patient, the history of onset, the sequence of the development of symptoms and the site at which they are experienced may aid in determining what is the most likely lesion.

Anatomy—The esophagus is a soft tube 9 or 10 inches in length composed of a thick outer muscular layer, a submucous coat and a mucous membrane. It reaches from the pharynx to the stomach. The upper end is guarded by a sphincter, the *cardiac sphincter*, which is largely derived from the inferior constrictor while the lower end has a similar sphincter where it passes through the diaphragm. In its course it presents several constrictions which must be considered during instrumental examination. They may be responsible for retention of foreign bodies and are frequently the site of pathological processes. The esophagus permits of considerable dilation; it is very delicate and may easily be ruptured by foreign bodies or careless manipulation of instruments. For purposes of description and on account of the differences in surgical accessibility the esophagus is usually divided into an upper or cervical, a middle or thoracic and a lower or abdominal portion.

Physiology—During the act of swallowing an active voluntary contraction of the pharynx and associated muscles of the floor of the mouth forces food downward. At the same time a stimulus is set up which relaxes the upper and lower sphincters and after this deglutition is continued as an involuntary act. The further passage of fluids is largely due to gravity but for the passage of solid food active peristalsis of the esophagus plays an important role.

The most common conditions requiring medical or surgical attention are congenital malformations, trauma, impaction of foreign bodies, corrosion, ulcers, chronic granuloma, cicatricial stenosis, spastic conditions, diverticula, varices and tumors.

CONGENITAL MALFORMATIONS

Congenital deformations are rare and of such a serious nature that most of the infants succumb during the first days of life.

Atresia of the esophagus with tracheoesophageal fistula comprises about three fourths of all esophageal malformations. Infants affected with such a condition usually die from starvation or from aspiration into the lungs. A few recent operative successes indicate progress in the treatment of this disorder. Congenital strictures may yield to the passage of bougies, but a gastrostomy may be necessary to bridge over the early period. Congenital shortness of the esophagus with an intrathoracic stomach is an interesting condition which may be mistaken for stricture. It is usually not discovered until later in life, either during a routine roentgenographic examination or because of symptoms. Appropriate treatment results in symptomatic relief.

TRAUMA

Injury to the esophagus by external violence is usually associated with serious damage to other viscera. Trauma from within may be due to an increase in intraesophageal pressure causing spontaneous rupture to the passage or impaction of a foreign body or to instrumental manipulation. Since the passing of rigid instruments blindly is avoided, the number of serious injuries is small at the present time. The passage of an esophagoscope is attended with a certain risk, and great care is therefore necessary at all times. In case perforation of the esophagus is suspected, early operation is indicated. The perforation usually occurs just above the cricopharyngeus muscle, and the resulting spreading infection is therefore accessible from the neck. Notable successes have attended early operative intervention combined with other appropriate measures such as rigid mouth hygiene, the use of zinc peroxide and chemotherapy.

IMPACTION OF FOREIGN BODIES

Most swallowed foreign bodies pass through the esophagus without difficulty. Large or irregularly shaped bodies, however, may become impacted at one of the normal anatomical narrowings (Fig 513) or at a pre-existing slight stricture, while sharp objects such as safety pins may be caught in the mucous membrane at any point. Impaction of a foreign body at once leads to complications such as acute obstruction, in-

flammation, edema, spasm of the sphincter and secondarily periesophagitis, mediastinitis, empyema, etc. (Fig 514). One should therefore consider every patient with an impacted foreign body to be in grave danger and should take immediate steps to give re-

Fig 513—Congest carcinoma in the upper portion of the esophagus of a child.

lieve. A roentgenogram is most valuable and may show the kind, size, shape and position of the object. A negative finding in a suspicious case is not conclusive and must be followed by esophagoscopy. One should be prepared not only to make a diagnosis but

Fig 514—Small object, safety pin, in the lower esophagus of a child. The point of the pin has perforated the esophagus and produced empyema on the right side.

to remove the offending substance. With skill, most foreign bodies can be removed through the esophagoscope. If the object is large and situated near or in the cardia, it is at times advisable to remove it from below through the stomach. Esophagotomy is rarely indicated.

CORROSION

Corrosion of the esophagus is caused by the ingestion of strong alkalis acids or hot fluids. Many patients die and in those who recover stricture formation develops. The immediate treatment consists in administering a neutralizing antidote and combating pain and shock as well as dehydration. A gastrostomy may be required. In order to counteract the tendency toward the formation of stricture the relatively early swallowing of a silk thread is advisable. This avoids complete stenosis of the esophagus and may later be used for the passage of bougies.

ULCERS

There is no definite line of division between ulcers of the esophagus and esophagitis because in many cases of esophagitis acute or subacute ulcers are present. Ulceration may result from a variety of causes such as stagnation of food in cardiospasm and stricture the passage of instruments or foreign bodies retention of feeding tubes and regurgitated acid gastric content. Most of these lesions respond to local and dietary treatment but the so called chronic peptic ulcers may lead to hemorrhage or perforation.

GRANULOMA

Tuberculosis syphilis actinomycosis and blastomycosis of the esophagus are occasionally encountered. They are usually secondary to involvement of other organs. They do not produce distinctive subjective symptoms and the diagnosis is usually made in connection with biopsy specimens obtained from one of the lesions. The treatment should be directed toward the general control of the disease aided by local applications or incision when feasible.

CICATRICAL STENOSIS

Benign strictures of the esophagus may be congenital or acquired. Acquired strictures may follow trauma corrosion esophagitis simple ulceration or chronic granuloma. The symptoms consist of dysphagia and regurgitation of food. The diagnosis is based on the history of ingestion of a corrosive substance or of a preceding trauma. By means of roentgen examination it is usually possible to differentiate between a benign and a malignant stricture. In doubtful cases

an esophagoscope examination is indicated. Treatment consists in gradual dilation by means of bougies. They may be passed from above or retrograde with the aid of a gastrostomy. On account of the danger of perforation bougies should not be passed blindly but only over a previously swallowed silk thread.

SPASTIC CONDITIONS

Spasm may occur in any portion of the esophagus. It is the result of disturbance of the delicate balance between the parasympathetic portion of the autonomic nervous system and the sympathetic portion which control the physiology and normal deglutition. There are two recognized clinical entities associated with spastic conditions of the esophagus. One affects the upper portion and is known as the Plummer-Vinson syndrome. The other affects the lower portion and is best known under the name of cardiospasm. The etiology is not clear but evidence is accumulating to indicate that spastic conditions are due to a neuromuscular dysfunction. Recent investigations have unearthed many facts which support the theory that nutritional and vitamin deficiencies play an important role in the etiology. (See section on Cardiospasm.)

DIVERTICULA

Diverticula are sac-like dilatations which project from the wall of the esophagus. They are classified into pulsion and traction types but a combination of the two may occur. Pulsion diverticula are supposed to be due to pressure from within which gradually produces a hernia or bulge of mucosa and submucosa at weakened portions of the musculature or at the points of penetration of blood vessels. Traction diverticula on the other hand as the name implies are supposed to be due to a pull from without usually by attached tuberculous mediastinal lymph nodes. Diverticula are most often encountered at the junction of the hypopharynx and esophagus about the middle of the esophagus and just above the diaphragm.

Pharyngoesophageal diverticula are the best known because of their frequency and clinical importance. They arise from the posterior pharyngeal wall just above the cricopharyngeus muscle and may reach a large

size (Fig 515) The symptoms depend largely on the size of the diverticulum and consist of difficulty in swallowing and regurgitation of food There is also frequent cough from aspiration as well as loss of weight from nutritional disturbance The diagnosis is readily made by roentgen examination if the condition is suspected Surgical treatment consists of extirpation of the sac The operation may be done in one or two stages Individual opinion the experience of the operator the size of the diverticulum and the general condition of the patient will determine the decision in favor of a one or two stage procedure

Supradiaphragmatic diverticuli are also usually classed as pulsion diverticuli They

Fig 515—Large esophageal diverticulum filled with barium

are much less common than those arising at the junction of the pharynx and esophagus The symptoms simulate those produced by cardiospasm and may be relieved by instrumental dilation of the cardia Operative intervention is dangerous and is indicated infrequently Under consideration comes trans thoracic extirpation of the sac or abdominal esophagogastrostomy

Traction diverticuli are not uncommon They are usually small and situated at the anterior wall of the esophagus in the neighborhood of the bifurcation of the trachea They usually produce no symptoms and are discovered accidentally during a routine roentgen examination of the esophagus They do not have a dependent sac and con-

sequently do not allow stagnation of food No surgical treatment is indicated for traction diverticuli as such It is only when acute suppuration takes place that a drainage operation may become necessary

VARICES

Esophageal varices are a common cause of serious bleeding from the esophagus They are usually encountered in cirrhosis of the liver or other conditions which produce portal hypertension The best method of establishing the diagnosis of esophageal varices is by roentgen visualization Attempts have been made to treat the condition either by a direct attack through the esophagoscope or by surgical intervention through the abdomen Surgical diathermy has been applied through the esophagoscope and lately esophageal varices have been successfully injected with a sclerosing solution The object of surgical intervention through the abdomen is to interrupt the venous channels between the portal system and the esophageal veins Ligation of the coronary vein and the vasa brevia of the spleen with or without splenectomy may be effective

TUMORS

Benign tumors of the esophagus are rare and of little clinical interest Symptoms are usually present only when the growth is large or when multiple tumors are present The diagnosis can be definitely established only by means of esophagoscopy and biopsy Benign growths of the esophagus only rarely require external operation with esophagotomy Small tumors may be removed with biting forceps manipulated through the esophagoscope Pedunculated tumors may be snared off Occasionally the entire tumor may be destroyed by electrocautery or surgical diathermy

Sarcoma of the esophagus is a rare lesion and in many of the reported cases there is some doubt concerning the exact pathology The treatment of sarcoma is identical with that employed for carcinoma but to date no case of sarcoma has been treated successfully by radical operation Radiotherapy may be employed for palliation especially for lymphosarcoma

Carcinoma of the esophagus is a common disease According to different statistics

esophageal carcinoma constitutes from 4 to 10 per cent of all malignant growths. It is a rapidly fatal disease and is therefore one of the most important disorders of the esophagus. Carcinoma may occur at any level. The onset is insidious and for this reason medical aid is rarely sought until dysphagia has become manifest. Even then this symptom is often not given the necessary attention and the disease is allowed to progress until regurgitation of food, salivation, pain and loss of weight occur. All of these symptoms are late manifestations and at least partly explain why surgical treatment of cancer of the esophagus has not made more rapid progress.

Diagnosis—In experienced hands the diagnosis is usually easily made by means of roentgenograms which in a typical case show an irregular deformity with slight dilatation above it (Fig 510). Errors in diagnosis are easily made however and it is therefore important to perform a biopsy.

Treatment—Carcinoma of the esophagus usually comes under a surgeon's observation when the disease is far advanced locally and when as a result of malnutrition the patient has become emaciated and dehydrated; hence the treatment of this condition in most instances is limited to palliative measures. These consist of general medical care, the performance of gastrostomy, dilation of the malignant stricture, intubation, electrocoagulation and radiation therapy.

With the present state of our knowledge and with the type of patient referred to the surgeon, only a small group of carefully selected cases may be considered for radical operation. The pioneers in this field have established the feasibility of the operation and reliable autopsy reports on patients dying as the result of carcinoma of the esophagus have shown that at least 25 per cent have no demonstrable metastases. This knowledge should encourage surgeons to undertake the operation. Progress made during the last few years in anesthesia and chemotherapy has helped a great deal in the avoidance of serious complications. Improved preoperative and postoperative care have also been important factors. Every case requires careful study and adequate preparation with a view to utilizing all safeguards before the operation is undertaken. Because of various

technical and physiologic problems encountered in operations on different portions of the esophagus it is best to consider treatment of these different segments separately.

1 Carcinoma of the Cervical Portion of the Esophagus—The lesion may be removed from above. At times the larynx and pharynx must be sacrificed; a reconstruction operation may be considered later. Gastrostomy is usually advisable. The operation is a formidable one and in view of the good results occasionally reported from external radiation in cervical esophageal carcinoma such treatment may be preferable.

2 Carcinoma of the Thoracic Portion of the Esophagus—Cancer of the middle por-

Fig 510—Typical carcinoma of the lower esophagus showing irregular outline of the obstructive lesion.

tion is technically the most difficult and dangerous to remove. During the last few years the operation has been successfully performed with increasing frequency by surgeons in all parts of the world. Most often the transpleural method described by Torek is employed. After preliminary gastrostomy the thorax is opened wide along the seventh intercostal space. The esophagus is divided below the tumor and the lower end is invaginated into the stomach. The upper portion of the esophagus with the tumor is then completely freed and brought out at the neck. After removal of the involved segment the upper esophageal stump is drawn through a tunnel beneath the skin to form an esophagostomy. By means of a rubber esophagus the esophagostomy and the gastrostomy are

Fig. 517—*a* Patient after resection of the esophagus showing Jareway gastrostomy opening and subcutaneous upper end of esophagus on chest wall *b* with rubber esophagus in place

then connected to permit swallowing (Fig. 517). A reconstruction operation may be considered later.

3. Carcinoma of the Lower Portion of the Esophagus and the Cardia—Because of the possibility of restoring normal function operations for carcinoma of the lower portion of the esophagus are more favorable than those for cancer situated at a higher level. Depending on its extent the lesion may be approached through the abdomen, through the thorax, or by a combined abdominal-thoracic incision. In view of the uncertainty concerning the upward extension of the growth the transpleural route is usually preferable. The incision is made along an intercostal space or through the bed of the eighth or ninth left rib. The diaphragm is split and the upper end of the stomach, the cardia and lower portion of the esophagus is mobilized. After resection of the tumor-bearing area the stomach is closed and the fundus is drawn up into the thorax and fastened behind the esophageal stump. The latter is then implanted into the fundus usually with the aid of two rows of interrupted silk sutures. Direct continuity of the alimentary canal is thus re-established. It has been found that by adequate mobilization of the stomach the fundus can be brought fairly high within the thorax and

the establishment of a safe and satisfactory esophagogastronomy permitted. Application of this procedure has therefore been extended to include some cases in which the Torck operation was formerly deemed necessary.

Operative Results—Definite progress is being made in the surgical treatment of carcinoma of the esophagus. Numerous successful cases have been reported singly or in small groups in the American as well as in the European literature and they hold out the hope that this dreaded disease is gradually being conquered.

CARDIOSPASM (ACHALASIA)

Idiopathic dilatation of the esophagus without anatomic stenosis more commonly designated as cardiospasm is second in frequency in carcinoma in producing symptoms of esophageal obstruction.

It is a condition in which there is a constant spastic contraction of the cardiac portion of the esophagus without anatomic stenosis but with more or less dilatation of the esophagus above the point of obstruction. The cardinal symptoms of the disease are epigastric pain dysphagia and regurgitation. Frequently such pulmonary symptoms as cough expectoration fever and asthmatic seizures result from aspiration of portions of the content of the esophagus or from pressure of the esophagus filled with food.

The etiology of the disease is not known but a disturbance in the nerve muscle mechanism of the esophagus and cardia is the most likely cause. The disease may begin either gradually or suddenly and it may occur at any time of life. It is questionable whether contraction at the cardia observed in infants a few days old represents true cardiospasm although authentic cases of cardiospasm have been seen in children two years of age. There are slightly more males than females affected with the disease.

Cardiospasm is not a neurosis and persons with a nervous temperament are no more susceptible to the disease than those of a phlegmatic type. It seems that the disease is primary in the majority of instances although one occasionally observes associated lesions in the appendix stomach or gall bladder. When such a lesion is observed in association with cardiospasm it should be considered merely as coexistent elimination

of intra abdominal disease rarely affords relief from the symptoms associated with cardiospasm.

Between 60 and 70 per cent of sufferers from cardiospasm experience some degree of epigastric pain. In many instances this is severe and may require hypodermic injections of morphine for relief. The pain must be distinguished from that arising from gall stone or from angina pectoris.

Dysphagia may vary in intensity but it is present at almost every meal. As a rule the patient experiences more difficulty with liquids than with solid foods and cold water seems to cause more distress than other liquids.

Regurgitation usually occurs immediately after swallowing in the early stages of the disease. Later however when the esophagus becomes more dilated the ejection of food may be delayed for longer periods of time. Nocturnal regurgitation and aspiration of food and mucus may be particularly annoying and may result in loss of sleep or in the production of acute or chronic pulmonary suppurative disease.

Cardiospasm should be suspected when the cardinal symptoms have been present for more than a year and when there is no history of the ingestion of a caustic which might have produced a cicatricial stricture. Roentgenologic study will reveal a smooth obstruction at the cardia with more or less dilatation of the esophagus above this point. The passage of a 41 French sound over a previously swallowed twisted silk thread is accomplished without detecting obstruction. It would be the case if carcinoma or an inflammatory lesion were the cause of the stricture.

Esophagoscopy is of value in differential diagnosis and should be carried out whenever there is any question as to the cause of obstruction. Medical treatment rarely affords even temporary relief from symptoms and the results from surgical exploration of the cardia have not been encouraging. Plastic operation on the cardia entails a grave risk and should not be undertaken. Efforts have been made to remove the sympathetic nerve supply of the cardia and some authors have reported favorable results. However lack of knowledge of the exact nerve supply of the esophagus makes the value of this

method doubtful. Mechanical dilation of the cardia with a 60 French sound will provide temporary relief for 10 per cent of those suffering from cardiospasm, and almost all of those having recurrences after this treatment and the ones who are not benefited by it can be cured by dilating the cardia with the Russel hydrostatic dilator. The risk of stretching the cardia with this expanding

dilator after the passage of a 60 French sound is negligible

XXV. THE ABDOMINAL WALL

DESMOIDS OF THE ABDOMINAL WALL

(*Fibromas of the Musculofascial Layers of the Abdominal Wall*)

Definition.—The term "desmoid" is commonly used with reference to the tumors found in the abdominal wall, although Masson states that at the Mayo Clinic they include in the classification tumors from musculoaponeurotic structures elsewhere as well. The commonest site is the rectus muscle. The situation is more often below than above the navel.

report of one of the writer's cases stated: "The specimen appears for the most part encapsulated" Pfeiffer speaks of encapsulation. From the practical surgical standpoint, it is undoubtedly easy to leave infiltrating portions of the tumor in the surrounding musculature, occasionally they are found to be adherent to the periosteum of an adjacent bone.

The growths are firm and cut with a grating sound. Not infrequently, according to Ewing, the structure resembles neurofibroma with intertwining bands of fibers and cells. He states that the structure varies from a

Fig 318—Mrs M B (see text) Desmoid tumor of the right rectus muscle, first noted nine months after confinement

Etiology.—Pfeiffer, who collected the records of 100 cases, found that 87 per cent were in women, 94 per cent of whom had borne children. The greatest incidence in women is in the child-bearing age. These facts indicate that pregnancy is an important predisposing factor. Sears of previous laparotomies are also a recognized site (3 of 39 abdominal cases reported by Masson). He also reports a case in which a tumor developed in apparent relation to a direct injury of the biceps of the arm. Such facts support the theory that trauma is an important etiologic factor.

Pathology.—Masson says that these tumors are not encapsulated. The pathologic

hard acellular fibroma to a rather cellular fibrosarcoma. It should be emphasized, however, that desmoids are not malignant tumors and, while prone to local recurrence, do not metastasize. Sarcomas should not be included in the group.

Symptomatology.—The patient may experience discomfort from the presence of the lump, but otherwise there are no characteristic symptoms.

Diagnosis.—Desmoids are uncommon tumors. Masson reported 50 cases, of which 39 were in the abdominal wall, from the records of the Mayo Clinic in the course of nineteen years. They are to be distinguished from other tumors of the abdominal wall, inflam-

matory masses and intra-abdominal tumors. Two cases in the writer's practice will serve as illustrations.

M B., a woman of about thirty, had noticed a lump three years before admission and nine months after confinement. The lump had enlarged and given occasional twinges of pain. Examination showed that there was a mass about the size of an orange just to the right of the midline below the navel. It was at first thought to be an intra-abdominal tumor, but careful examination showed that it was situated in the abdominal wall. At operation it was found to involve the inner two thirds of the right rectus muscle with its sheath extending from the umbilicus almost to the pubis. The peritoneum was sufficiently adherent to be opened in the dissection.

M Y. was a woman of thirty-nine. She had had a previous laparotomy. She complained of pain and for two weeks had noticed the presence of a lump. On examination a mass the size of a lemon was found to

Fig 519—Mrs M B (see text). The desmoid tumor sectioned.

be situated deeply in the upper end of a low midline scar. It was matted and slightly tender. A provisional diagnosis of endometrioma was made. At operation the tumor was found to arise from the rectus muscle and its posterior sheath.

Prognosis.—The prognosis is excellent, but local recurrences may develop. This happened in 3 of 26 cases of desmoids of the abdominal wall followed at the Mayo Clinic. Pfeiffer, whose paper appeared in 1904, reported 21 per cent recurrences in women and 68 per cent in men.

Treatment.—Treatment consists of excision. Masson states that radiotherapy alone has not been successful in curing these tumors but may be used as a supplement to surgery. This is particularly desirable when it has not been possible to remove the growth completely. Removal of the tumor

may leave a large defect in the musculature of the abdominal wall that is difficult to close. This was the situation in the first of the writer's cases reported above. Closure was effected with the help of three fascial strands from the patient's thigh, which were sutured back and forth over the defect. The result as far as the patient has been followed (about one year) has been satisfactory.

PILONIDAL SINUSES AND CYSTS

(*Sacrocoecygeal Ectodermal Sinuses and Cysts*)

Definition.—A pilonidal sinus is a congenital stratified squamous epithelium-lined sinus, with or without cystic formation, occurring in the soft tissues overlying the site of the sacrocoecygeal hiatus. It is manifested by a single or multiple openings on to the skin (in rare cases openings may be absent), varying in size and located in the midline, with or without tumefaction beneath or slightly cephalad to the sinus openings. Immature hair shafts may or may not protrude from the sinus openings. There may be secondary sinus openings in the midline or lateral to the midline resulting from infection and abscess formation in the sinus or its cystic counterpart (Fig 520).

These sinuses may be divided into (1) true pilonidal sinuses and (2) sacrocoecygeal dimple and dimple sinus (Fig 520, b, d, a, c). These sinuses and cysts are of common occurrence from infancy to old age.

Etiology.—Everyone is in agreement that these sinuses and cysts are congenital in origin, however there is considerable disagreement as to their formation (Mallory, Oehlcker, Tournoux and Hermann, Aschoff, Gage, Stone and Fox). There are three principal theories, each being championed by various authors: (1) cystic remnants from the caudal end of the medullary canal (Tournoux and Hermann, Mallory and Gage); (2) faulty development of the mesoderm in the sacrocoecygeal region, producing dermal inclusions (Lannelongue, Aschoff, Fox and others), and

(3) inclusion of dermal developmental structures analogous to the preen gland of birds (Stone) The

Tourneaux and Herrmann have demonstrated epithelium lined cysts in the sacrococcygeal area in a large

Fig 520.—Photographs demonstrating the various types of pilonidal sinuses and cysts and their complications. *a* simple sacrococcygeal dimple sinus. *b* and *d* uncomplicated and non suppurative type. *e* sacrococcygeal dimple sinus with accessory sinus opening near anus. *e* and *f* accessory sinus secondary to abscess formation. author agrees with Mallory. Tourneaux and Herrmann that these sinuses and cysts have their origin from the caudal appendage of the medullary canal. Mallory,

number of fetuses which may or may not have connections with the skin surface. After many years of investigation the author is convinced that the theories

of Mallory, Tournoux and Hertmann can be substantiated and accepted. That these sinuses and cysts are intimately associated with the development of the medullary canal is also substantiated by the case reported by Walker and Bucy. These authors report a case in which the sinus was at the level of the fourth dorsal vertebra. The sinus tract extended from the skin surface to the cord proper.

The sacrococcygeal dimple and dimple sinus results from maldevelopment of the caudal ligament. The caudal ligament arises from the tip of the last coccygeal vertebra and is attached to the skin of the tail bud anlage. If the development of the caudal ligament does not proceed normally, the ligament remains short and pulls the skin into the form of a dimple over the coccygeal area. If this malformation becomes excessive, the dimple is converted into a dimple sinus (Fig. 520 a). The author has demonstrated this to be true in a number of cases by undermining the tissue beneath the dimple. There followed immediate disappearance of the dimple which assumed the level of the surrounding skin.

The sacrococcygeal dimple and dimple sinus as well as the true pilonidal sinuses and cysts occur predominantly in the white race; their occurrence is said to be comparatively rare in the Negro. However, the author has seen a number of cases in the Negro and the occurrence in this race is probably more common than reported. The Negro is less prone to cutaneous infections than the Caucasian; therefore if he has a pilonidal sinus or cyst, it is less likely to produce symptoms. It is estimated that about 5 per cent of the white race have pilonidal sinuses or cysts. In the Army, an operation for pilonidal sinus and cyst is one of the most common if not the most common, elective surgical procedure.

Pathology—There has been considerable disagreement as to the histology of these interesting but simple sinuses and cysts occurring in the midline of the sacrococcygeal region. The simplest form is the sacrococcygeal dimple. These dimples are very common and present little cellular pathologic evidence. There is, however, a peculiar phenomenon in that the epidermis of this lesion has no hair follicles. This is called the "sacral hair spot" of the embryo by Ohlcker and the author has confirmed these findings. The sacrococcygeal dimple sinus points caudad and occasionally extends down beside the rectum as far as the external sphincter. A cystic dilatation of the caudal terminus may become several centimeters in diameter. The ano-rectal terminus of this sinus may be situated in the midline or laterally placed either to the right or to the left of the midline and in juxtaposition to the rectum. Hairs seldom protrude from the sacrococcygeal dimple sinus opening (Fig. 520 a). When infection and abscess formation occur within this sinus, a secondary sinus may develop which may simulate a fistula-in-ano (Fig. 520 c). These sacrococcygeal dimple sinuses are not common and secondary infection with abscess formation is of infrequent occurrence.

The true pilonidal sinus and cysts however present a different pathologic picture. The sinus tract may be situated superficially, just beneath the true skin, or deep in juxtaposition with the perineum over the sacrococcygeal area. The direction of the sinus tract

is always cephalad. There may be a single opening but usually there are multiple openings in the midline (Fig. 520 b d to h). Occasionally the openings may show cleft formation (Fig. 520 d). The sinus may be very short without associated cystic formation (Fig. 520 b). However, the sinus may be quite long and may extend upward in the midline or to either side. This lateral deviation is seldom of great distance from the midline. In many instances the cystic or bulbous end may extend up over the sacrum for some distance (Fig. 520 g). A somewhat similar condition exists in the two cases depicted in figure 520 e and f. In rare instances the sinus tract may extend into the sacral canal for a varying depth and even may be attached to the dura or continuous with it. Cases of this type have been reported by Mose, Ripley and Thompson and Gage. When the sinus tract is continuous with the dura (very rare instance) spinal fluid may or may not escape via the sinus tract. It is also conceivable that if the sinus tract is in juxtaposition with the dura, secondary infection of the tract may result in pyogenic meningitis.

The sinus tract and its cystic dilatation or bulbous tip is lined with stratified squamous epithelium. This epithelial lining extends through the entire sinus and its bulbous or cystic counterpart and is continuous with the normal skin at the dermal openings of the sinus. Numerous hair follicles develop from the epithelial lining and fine immature hairs protrude into the sinus lumen at times filling up the sinus and its cystic portion; hence the name *pilonidal cyst*. The epithelium in the majority of all cases reveals long-standing infection of the cornified layer with cracks and fissures extending through the epithelial lining. The perianal tissues show varying degrees of inflammation, both acute and chronic, characterized by infiltration of polymorphonuclear lymphocytes and plasma cells, with an occasional foreign body giant cell. The connective tissue surrounding the sinus tract reveals considerable productive fibrosis due probably to the ever present chronic infection. The collagen fibers are wavy and compact, simulating keloid formation. Granulation tissue is frequently seen budding into the lumen of the sinus through the cracks and fissures of the epithelial lining. Occasionally the sinus is almost completely devoid of its epithelial lining. In the latter instance the walls of the sinus and the lining are composed of granulation tissue.

In a histologic study of specimens in 80 cases, the author has noted no sebaceous or sweat glands arising from the stratified epithelial lining. However, both sweat glands and sebaceous glands have been seen in juxtaposition to the sinus tracts. By making serial sections of the specimens, these glands can be traced to the overlying normal skin of the sinus tract. When the sinus tracts or cysts are superficial, sweat glands and sebaceous glands from the normal skin covering penetrate to either side of the sinus tract.

Acute infection of the sinus tract resulting in abscess formation is of common occurrence. A more serious complication, fortunately rare, is carbuncle formation of the sinus and overlying integument. When the sinus and/or its cystic counterpart are superficially located and abscess formation occurs, it points in the center. Whereas when the sinus and its cystic portion are

deeply situated abscess formation usually points laterally, to the midline (Fig 520 e and f). When the abscess occurs within the sinus tract, the epithelial structures are frequently destroyed. The same can be said of carbuncles. When the abscess occurs in a superficially placed sinus or cyst, the abscess points and ruptures (or is incised surgically) resulting in a secondary sinus in the midline (Fig 520 g). When the sinus or its cystic counterpart is deeply situated and an abscess develops within the sinus, it ruptures (or is incised) forming a secondary sinus lateral to the midline (Fig 520 e, f, h).

Occasionally, a pilonidal sinus or cyst is found which has no openings on the overlying skin surface. However, there is as a rule a small timefaction in the midline near the sacrococcygeal junction. On careful inspection with the skin stretched (Fig 520 e), one or more bluish spots of millimeter size can be seen with the epithelium at these sites only one cell thick. If the sinus or cyst is more deeply situated, a small tumor mass is then the only indication of its presence. Fortunately, this type of pilonidal sinus is rare.

Symptomatology—The symptoms of a complicated pilonidal sinus and cyst are practically nil, with the result that a great majority of individuals go through life not cognizant of having this malformation. There are, however, several signs that denote the presence of a pilonidal sinus: 1. Single or multiple small openings occur in the median raphe of the skin overlying the sacrococcygeal area. 2. Hairs may or may not protrude from these openings. 3. An occasional discharge (desquamated epithelium and secretions from low grade non-symptomatic chronic infection) soils the patient's clothing. When symptoms are present, they are indicative of acute infection with or without abscess formation. When an acute abscess is present, the patient has severe pain in the sacrococcygeal area with general malaise. The abscess may point either in the midline (superficial sinus or cyst) or laterally to the midline (deeply situated sinus and cyst). There may be a slight elevation of the temperature depending upon the acuteness of the abscess and its intraluminal pressure. If a carbuncle develops in association with the sinus, the local and systemic reactions are more pronounced. This complication is fortunately comparatively rare, and the symptoms do not arise from the pilonidal sinus but from the superimposed acute infection. Therefore, it can again be reiterated that symptoms from an uncomplicated pilonidal sinus are very rare. This is very important and immediately suggests

that a pilonidal sinus or cyst must be sought for in all examinations of patients. Some patients have a pilonidal sinus or cyst that has no openings into the skin surface and they may also have secondary abscess formation within the 'blind' sinus or cyst. Patients that have pain or abscess formation midline in the sacrococcygeal area without a sinus should be considered as having a pilonidal sinus or cyst without a skin connection until proved otherwise. A patient with a sacrococcygeal dimple or dimple sinus is unaware of its presence unless it is complicated by abscess formation.

Diagnosis—The diagnosis is not difficult if it is remembered that the presence of one or more sinuses in the sacrococcygeal region denotes the presence of a pilonidal sinus or sacrococcygeal dimple sinus with or without concomitant cystic dilatations. If an abscess is present in the same location, either in the midline or lateral to the midline, the buttocks should be separated and a search made for sinus openings. Not infrequently, the patient gives a history of having had one or more abscesses in the sacral area. On examination, a secondary sinus may be found, its mouth being filled with a granuloma (Fig 520 e to g). All the photographs in figure 520 demonstrate the necessity of buttock separation to bring into prominence the pilonidal sinus area.

The differentiation between the true pilonidal sinus and the sacrococcygeal dimple sinus is not difficult. The direction of the true pilonidal sinus is always cephalad (Fig 520 e to g), whereas the direction of the sacrococcygeal dimple sinus is caudad (Fig 520 a and c). The only difficulty that may arise is in those cases in which a secondary abscess with sinus formation is near the anus (Fig 520 c). This type is frequently diagnosed as fistula in ano. If the nates are separated and the median raphe over the sacrococcygeal region is inspected, no mistake will be made.

To determine the extent of the sinus tract, a probe can be used, or the sinus tract and its cystic counterpart can be injected with an opaque substance. Roentgenographic evidence can be obtained of the extent and direction of the sinus and cystic dilatations. The examiner should always determine the extent of the tract because the cephalad

end may extend into the sacral canal and may be either attached to the dura or continuous with it. There may be diagnostic difficulties with the blind type of pilonidal sinus. However, if the nates are separated widely and the skin over the sacrococcygeal area is carefully surveyed through a magnifying glass, pinpoint bluish areas can be seen in the midline. A probe can readily be pushed through this thin skin and into the sinus and a small tumor mass may be palpated beneath the skin in the same area. A probe can also be inserted into the secondary sinus (Fig 520 c e f) and may be pushed gently into the pilonidal sinus and/or its cystic dilatation.

From a study of all the photographs in figure 520 it is readily seen that the diagnosis of pilonidal sinus can be made without difficulty.

Treatment—The treatment of pilonidal sinus resolves itself into categories: (1) those cases that are complicated by an acute abscess and (2) those cases in which there is no infection and/or those in which the infection has subsided resulting in secondary sinus formation. (See Fig 520 g for the acute abscess b for the non infected pilonidal sinus and c e to g for those in which the infection has subsided leaving secondary sinus formations as a residual.)

There is no disagreement in the treatment of the cases with superimposed acute infections such as abscesses and carbuncles. The treatment is primarily conservative and never radical. The procedure of choice is incision and drainage. The incision should be adequate to promote free drainage. In making the incision extreme care should be taken that the knife does not penetrate beyond the limiting epithelial covering of the posterior wall of the sinus tract. The post-operative treatment consists of frequent hot sitz baths and daily dressings of the wound. Sulfadiazine in 1 Gm. doses four times a day will aid greatly in overcoming the infection. If the infecting organism belongs to the coccal group penicillin can be instilled once a day into the abscess cavity as well as applied to the first layer of the gauze dressing. If a carbuncle involves the pilonidal sinus it should be treated by hot moist compresses. Penicillin should be given intramuscularly 200,000 Folex units every three hours

both day and night until the infection is overcome. The sulfonamide drugs may also be used.

No radical surgical procedure for the ablation of the sinus should be undertaken within two to three months of the acute episode. In a large number of cases the acute infection within the sinus destroys the epithelial lining of the pilonidal sinus with the result that no further trouble from the sinus is experienced by the patient a complete cure resulting. This desired result occurs only when the abscess points in the midline directly over the pilonidal cyst the superficial type described in the section on pathology. When the abscess points to the right or left of the midline a secondary sinus invariably results. This complication is well demonstrated in the accompanying photographs (Fig 520 e and f). The surgical cure of pilonidal sinus consists of complete eradication of the sinus, its cystic counterparts and accessory sinuses. The various procedures advocated for the cure of pilonidal sinus have become almost legendary. The constant flow of new procedures in the literature is the result of failures following the use of surgical procedures previously advocated. There are three procedures that are widely advocated today: 1 The open procedure in which the sinus is simply opened and the wound allowed to granulate and heal over. The Bane operation is the best one of this type and consists mainly of incising into the sinus tract leaving the epithelial lining undisturbed. The edges of the wound are sutured to the epithelium of the sinus tract. 2 The use of sclerosing fluids injected into the sinus tract. This is the method advocated by Cutler and Zollinger and many others. The author does not advocate this method of treatment. 3 Complete surgical removal of the pilonidal cyst, its cystic counterparts and its accessory sinuses with a minimal sacrifice of tissue and primary closure of the wound. The author considers this the procedure of choice. All of the numerous surgical procedures advocated have as their objective ablation of the sinus tract, primary closure of the wound and prevention of recurrences. However, the majority of these technical procedures are so complicated that they defeat their purpose. Extensive tissue removal, various plastic flap

designs and extensive undermining of the wound edges have not relieved the desired results. The type of operative procedure to be used must incorporate sound surgical principles i.e. the technic must be simple the sinus tract and its various counterparts must be completely removed absolute hemostasis must be obtained a minimal amount of adjacent tissue should be removed the wound edges must come together without tension all dead spaces must be obliterated and primary wound healing must be obtained.

The preoperative preparation consists first of determining the type and the extent of the pilonidal sinus. One of the sulfa drugs preferably sulfadiazine and vitamin C should be administered for at least four days before operation. Daily sitz baths are also advocated. The sinus tract can be injected with one of the colored dyes for the purpose of delineation. This is done as follows. The dye solution is injected daily for two or three days. Two days should elapse between the last injection and the day of operation. By means of this technic the tract is stained deeply by the fixation of the dye in its tissues the so called drying out process. At operation the sinus and its various ramifications are thoroughly stained and there is absolutely no staining of the surrounding tissues.

Operation.—The best type of anesthesia in these cases is low spinal anesthesia. If inhalation anesthetics are given a clear airway must be maintained throughout the operation because the patient is in the prone position. After the patient is anesthetized he is placed in the prone position with a pillow beneath the lower abdomen and pelvis. Wide adhesive strips are attached to each buttock pulled outward and downward and attached to the operating table. This gives a good exposure of the operative field by keeping the buttocks separated. The field of operation is widely prepared with mercuric iodine and thoroughly draped. Every precaution should be used to prevent contamination of the wound during the operation. This is essential since the operative field is adjacent to the anus. An elliptical incision is made very close to the sinus openings to prevent sacrificing any of the overlying skin (Fig 501 1). The incision is extended up-

ward in the midline the length corresponding to the length of the sinus tract. The incision is continued downward until the sinus tract is exposed. The dissection is then continued laterally and downward until the caudal end of the sinus tract is freed (Fig 501 2). The freed end of the sinus is now grasped with Allis forceps and sharp dissection is continued upward keeping close to the sinus tract until it is completely removed (Fig 501 2). If these simple rules are followed the pilonidal sinus is removed with a minimal sacrifice of tissue. If secondary sinuses are present (Fig 500 e and f) they are not disturbed until the primary sinus tract is removed. A probe can then be inserted through the secondary sinus from the skin surface into the wound. An incision is made over the probe and continued down until the sinus tract is exposed. The sinus tract is then dissected out with the probe in situ. This method does not sacrifice any tissue but the sinus tract. All bleeding points are ligated with fine cotton thread. Absolute hemostasis is necessary to prevent postoperative bleeding into the wound which inhibits wound healing and promotes infection. The wound is thoroughly irrigated with sterile normal saline solution and then dried with sterile gauze. Sutures of fine cotton (fine silk or fine catgut 0000 may be used non absorbable sutures are preferable) are used to approximate the deep tissues (Fig 501 3). The skin edges are now approximated with the interrupted Davis stitch (Fig 501 4). Tension sutures to obliterate dead spaces and to approximate the wound edges are not advocated because they have a tendency to interfere with the circulation in the wound edges thus preventing wound healing and increasing the tendency to infection. The operation described here so minimizes dead space formation that a simple pressure dressing agglutinates all wound surfaces. The wound is covered with several thicknesses of sterile gauze held in place by narrow strips of adhesive tape. A large stuffed out pad of sterile cotton waste is applied over the wound and fastened in place tightly with wide strips of adhesive tape that extend well down on the lateral aspects of the hips. This pressure dressing is most important because it obliterates all dead spaces prevents wound exudation and capil-

THE ABDOMINAL WALL

oozing and promotes rapid wound healing. The dressings should be sealed off from the anus with adhesive tape. If the sinus tract of the pilonidal sinus extends through the sacral hiatus and enters the sacral canal it will be necessary to unroof the sacral canal by removing two or

three vertebrae. This operation is more prone to develop because of its close proximity to the anus.

Postoperatively the patient should be kept in bed for ten to fifteen days depending upon the magnitude of the operation. A full diet can be given as soon as tolerated. Sulfadiazine is continued postoperatively for

Fig. 551.—A drawing depicting the surgical removal of a pilonidal sinus with minimal tissue sacrifice. 1 shows surrounding sinus opening. 2 sharp dissection of sinus tract with removal of a very limited amount of adipose tissue (the amount is exaggerated for definition). 3 closure of deep tissues with interrupted cotton sutures and 4 closure of skin incision with interrupted Davis stitches which prevents inversion of the skin edges.

of the sacral laminae. The operation is completed as previously described. The sacrococcygeal dimple sinus is treated in the same way as a pilonidal sinus. The only difference is that the latter sinus may extend to the anus being either anterior or posterior to the rectum. Postoperative infec-

tion is more prone to develop because of its close proximity to the anus. Vitamin C in 50 to 100 mg doses three times a day is continued for at least a month after operation. Vitamin C converts precollagen fibers into true collagen fibers producing sound wound healing. The patient should not return to full physical activity under four weeks.

Prognosis—The incidence of recurrence ranges from less than 1 to 50 per cent. The majority of recurrences are due to faulty technique in obliterating the dead spaces. These dead spaces fill with serum and exudate giving rise to wound separation and chronic infection which result in the formation of a granulomatous sinus.

If the operation is performed as described with minimal sacrifice of tissue and with proper application of the pressure dressing the incidence of recurrence should not exceed 1 per cent which has been the experience of the author.

WOUNDS AND CONTUSIONS OF THE ABDOMINAL WALL

The local treatment of wounds and contusions of the abdominal wall does not differ from that of similar injuries elsewhere; their great importance resulting from the probabilities of associated visceral injury.

Gunshot and stab wounds may be divided for purposes of consideration into those that penetrate and those that do not penetrate into the abdominal cavity. The difficulty lies in deciding into which group a given case falls as tenderness and rigidity may be manifested with a wound of the abdominal wall only as well as when intra-abdominal hemorrhage and visceral perforation have occurred. Therefore unless it is clear from the findings that there has not been penetration as for instance gutter wounds or those whose entrance and exit are so close together that it could not have taken place, one should consider the injury as potentially penetrating and treat it as such. The importance of this matter arises from the fact that the result in wounds of the gastrointestinal tract treated expectantly is likely to be a fatality whereas exploratory laparotomy in cases in which no visceral injury is found is attended by a low mortality.

Every patient therefore with an abdominal wound in which penetration is seriously suspected both from the apparent course of the missile and the presence of pain, tenderness and muscle spasm should be subjected to an exploratory laparotomy as soon as possible after appropriate attention has been given to shock, provided adequate hospital facilities are at hand. In military surgery it was formerly considered safer not to operate on a patient with such a wound but the experience gained in the first World War has reversed this opinion. Of primary importance is the length of time which elapses between the receipt of the injury and the patient's arrival at a field hospital equipped for aseptic surgery. In civilian life except in isolated areas the victim of a wound will be hospitalized within a few hours. As the time before treatment lengthens the outlook for recovery after serious visceral injury grows more unfavorable. Lee states that patients with general peritonitis from a hollow viscus injury twenty-four or more hours old are generally hopeless subjects for radical treatment and the expectant plan should invariably be followed. Munro in *Keen's Surgery* quotes Siegel who collected reports of over 700 cases of penetrating wounds of the gastrointestinal tract and found that the mortality varied from 15 per cent in those patients operated on within the

first four hours to 87 per cent when operation was delayed beyond twelve hours after injury.

Contusions of the abdominal wall may present a more perplexing problem than wounds as regards the question of visceral injury inasmuch as the patient may be shocked with pain vomiting tenderness and rigidity without as well as with intra-abdominal injury. Bottomley compared a series of 90 patients with abdominal contusion without visceral injury with 20 in whom it was associated and came to the conclusion that there is no sign or combination of signs sufficiently constant to indicate whether or not visceral injury is a part of the picture. His conclusion in which one must concur is that in severe cases with signs suggestive of intra-abdominal injury exploratory laparotomy should be promptly performed.

The following case in which a tragedy was barely averted illustrates the difficulties of diagnosis as well as the importance of exploration in case of doubt. A forty-year-old workman was struck forcibly in the lower abdomen by a board and was knocked down. He went to a physician's office where he faintly. He was admitted to the hospital three hours after the accident complaining of constant sharp pain in the lower portion of the abdomen. On physical examination he was lying quietly in bed in moderate discomfort. There was tenderness in the lower portion of the abdomen most marked on the left side accompanied by local spasm and rigidity. The epigastrium was relatively soft. Rectal examination afforded no further information. There was no break in the skin. The temperature on entry was 99.1° F. rectal temperature 99.2° and white blood cell count 11,600 with 88 per cent polymorphonuclears. The surgeon did not think immediate laparotomy indicated on the evidence presented but felt sufficient uneasiness to return for further examination a few hours later. By this time the temperature had risen to 101.8° F. and the blood count to 20,000 with 86 per cent polymorphonuclears. Even then the abdominal signs did not seem altogether clearcut, but exploration was decided on. A perforation of the small bowel 6 cm. in length was found with intestinal contents in the peritoneum. The postoperative course was marked by persistent low fever indicating a considerable degree of peritonitis but the patient finally recovered and left the hospital on the twentieth postoperative day. In retrospect it is easy to say that this patient should have been operated on at once on admission to hospital but it is not so easy to recognize the difficulty in recognizing the seriousness of the situation at the first examination.

In every case of abdominal contusion whether or not there are abdominal signs

the urine should be examined for blood as evidence of injury of the urinary tract. If the patient is able to void little or not at all the question of rupture of the bladder must be further investigated.

A blow in the epigastrium for which the patient is unprepared may be followed by immediate shock as evidenced by pallor sweating faintness and breathlessness popularly known as having his wind knocked out. Recovery is ordinarily prompt.

Among injuries of the abdominal wall special mention must be made of rupture of the rectus muscle and deep epigastric vessels. These cases are often called spontaneous hematomata of the abdominal wall. Although there are reports in the literature of rupture of the vessels without mention of muscular rupture it would seem that ordinarily the two conditions go together. The tearing of the muscle involving the epigastric vessels or their branches. The commonest site is below the navel where the muscle is said to be weaker. Wohlgenuth collected reports in 127 cases 107 of which resulted from considerable bodily effort such as jumping lifting and the like occurring mainly in young men. Cases also develop during pregnancy and labor and in debilitating diseases particularly typhoid. A rupture may take place however when a person is in apparently good health as a result of some trivial cause or with no apparent explanation. The patient often in older women complains of the sudden onset of pain with perhaps vomiting and faintness. Examination may reveal a mass due to the effusion of blood tenderness and spasm. The importance of these cases rests in the fact that they are often mistaken for intra-abdominal diseases such as acute appendicitis or ovarian cyst with twisted pedicle.

Morton reported such a case from St. Luke's Hospital in a man of twenty-eight who did not have a convincing history of trauma. The patient was thought to have acute appendicitis but at operation the appendix was found to be normal and a dark mass was seen bulging into the abdominal cavity under the right rectus muscle. The internal incision was closed and a second incision was made in the rectus disclosing a large hematoma and a bleeding point in the deep epigastric vein.

A second case from St. Luke's Hospital was that of a man aged sixty-three who noted a swelling in the abdominal wall while undressing four days before ad-

There was a tender fluctuant mass below the navel to the left. It was thought to be an abscess but at operation it proved to be a large hematoma originating in the deep epigastric vessels.

Because of the difficulties of diagnosis many of these patients will have to be operated on but if the diagnosis is clear if the hematoma is small and not increasing in size and if the symptoms are mild rest may be all that is required. Otherwise evacuation of the clot ligation of the bleeding vessel and suture of muscle if necessary should be carried out.

An excellent article on hemorrhage into or beneath the rectus abdominis muscle by Cullen is recommended to the interested.

SURGICAL AFFECTIONS OF THE UMBILICUS

Infections in the Newborn—Since the advent of aseptic surgery sepsis originating in the umbilical stump has become relatively rare. It still occurs occasionally however and the possibility should be borne in mind in obscure illnesses in infants. The pyogenic cocci and colon bacilli have been the commonest invaders while tetanus from this source is not unknown. Invasion is by the umbilical arteries veins or lymphatics. Peritonitis may arise from direct extension.

The infant appears healthy for several

days after birth until it becomes evident by loss of weight irritability and very possibly a gastrointestinal upset that he is not well. Examination of the umbilical stump may explain the cause on the other hand general sepsis can arise at this point without being evident on inspection. The outlook is serious. It is apparent that prevention by careful aseptic treatment of the umbilical stump in the newborn is of utmost importance.

The treatment of the disease once it appears is that of sepsis in general drainage of any collection of pus that may form and supportive measures among which blood transfusion is important.

Hemorrhage—Hemorrhage from the umbilicus is not of common occurrence taking place most often at the time of the separation of the cord. It is more likely to occur in cases of infection. Besides local measures such as compression and ligation blood transfusion is indicated.

Granuloma—Granuloma of the umbilicus is the result of incomplete healing after separation of the cord. Ligation of the base excision and the application of silver nitrate suffice for the cure.

The appearance may suggest a polyp. In one such case in a seven week old infant the tumor 0.5 cm. in diameter seemed at the first examination to be covered with epithelium. In order to be on the safe side treatment was given in the operating room so that a more extensive surgical procedure could be carried out if the condition proved to be a vestigial remnant with no abdominal connection. It was so clear that the mass consisted of granulation tissue it was treated in the usual way with prompt cure.

Infections—Infection of the umbilicus due to retained secretions are the commonest affections of the navel aside from hernia (see section on *Hernia*) encountered in adults. The deep recess with a narrow outlet favors the accumulation of sebaceous material in which hair and particles from the clothing may be mixed and the accumulation acting as a foreign body sets up an inflammation. Pain redness swelling induration tenderness and a purulent discharge ensue. The treatment consists in the removal of the foreign body which eliminates the source of irritation and allows drainage.

Persistence of Embryological Structures—Affections of the umbilicus due to

peristence of embryological structures although rare should not be forgotten by the surgeon. The omphalomesenteric or vitelline duct connecting the yolk sac with the digestive tract and the allantois from which the bladder is formed pass through the navel in early fetal life and occasionally remain wholly or in part as anomalous conditions.

A remnant of the omphalomesenteric duct may be present as a polyp sometimes called an adenoma and usually becomes apparent when the cord separates. The covering is of intestinal mucosa; it is red and secretes a mucoid fluid. The center consists of smooth muscle. If the vitelline duct has remained patent an opening will be found in the polyp. The opening may communicate with the bowel and cause the consequent leakage of feces. Cases of prolapse of the bowel through a patent vitelline duct are on record. In the case of a polyp the pedicle may be ligated and the polyp cut away. If there is a fistula the abdomen will have to be opened and the fistulous tract removed along with the navel.

A congenital vesical fistula which opens at the umbilicus is due to a patent urachus. After the patency of the urethra has been established the tract should be dissected out and removed together with the navel.

Urachal cysts present between the umbilicus and the symphysis. An infected urachal cyst or cavity may discharge at the navel and even open a communication with the bladder.

Tumors of the Navel.—Tumors of the navel of various types are recorded but are rare. It is one of the sites where endometrioma has been found. Carcinoma in this situation is usually secondary.

In the surgical records of recent years at St. Luke's Hospital there are reports of two cases of umbilical lesions other than hernia which came to operation illustrating the rarity of these conditions. In both instances the pathologic diagnosis was epidermoid cyst. The case report of one of these patients will serve as an illustration. The patient was a boy of six years who had had since birth an irreducible swelling at the navel. At operation Dr. Douglas removed a cyst containing cheesy material. The microscopic examination showed a thin lining of flattened squamous epithelium.

The writer wishes to acknowledge his indebtedness to Dr. T. S. Cullen's admirable and exhaustive book (*The Umbilicus and Its Diseases*, Philadelphia, W. B. Saunders Co. 1916) from which he has drawn almost exclusively in preparing this section.

LT COL MORRIS K. SMITH

XXVI THE PERITONEUM

The peritoneal cavity is the largest cavity in the body. Like the pleura and the tendon sheaths the peritoneum is a serous membrane which is derived from the mesenchyme and is not epithelial in nature. It does not behave like epithelium either in function or in repair. The cells which form the peritoneal surface are flattened and polygonal and are separated from each other by a small amount of cement substance which can be stained with silver. The cells are similar everywhere except on the surface of the great omentum where the cells which do not rest upon fat form a synestium so that the organ when first removed from the peritoneal cavity has the appearance of a moist silver screen. Beneath the mesothelium in the parietal portions is a layer of loose fatty connective tissue called according to its location preperitoneal fat or retroperitoneal fat. Elsewhere for the most part the mesothelial cells lie upon a small amount of subserous tissue which covers the intra-abdominal organs. It is the subserous layer whether fatty or not which is the site of most of the activity of the peritoneum. In it lie the enormously rich capillary beds for the blood and lymph from which all nourishment must come and through which all absorption and exudation must take place. In this layer also are initiated most of the processes of repair.

FUNCTION OF THE PERITONEUM

The peritoneum has a surface approximately equal to that of the skin. It is smooth and moist so that parts of its surface glide easily over one another. It has great capacity for absorption both of fluids and of small particles. As in other parts of the body absorption of fluids in general takes place most rapidly if they are isotonic with the body lymph. When fluids which are not of this character are introduced into the peritoneal cavity they are usually altered to isotonicity before much absorption takes place. The speed of absorption even of particulate matter is amazing. The process

is often recognizable in a few minutes after the substance is introduced. Another function is that of transudation or exudation. The peritoneum is not thought of as secreting as do epithelial cells. Probably this happens to some extent but the more important action is the transmission in a relatively unaltered state of substances which are brought by the blood or lymph. The peritoneum like other soft mesenchymal tissues also takes part in the processes of inflammation and repair.

INTERDEPENDENCE OF PERITONEAL AND THORACIC CAVITIES

The peritoneal and thoracic cavities are usually treated as if they were remote from each other but the main body cavity is one which extends from the apex of the pleura to the hollow of the pelvis. It is divided only by the thin flexible diaphragm. The upper functional apertures can be thought of as the glottis and pharynx and the lower as the sphincters of the bladder and the anus. In the quiet act of breathing the contraction of the diaphragm increases the intra-abdominal pressure and the relaxed abdominal muscles are pushed forward. In the more complicated acts of coughing or straining the sphincters and the glottis must act in harmony or the contents of bladder or rectum may inadvertently be extruded. The same is true of the contents of an abdominal hernia of any kind. Conversely when the action of the diaphragm is embarrassed by distended abdominal viscera or by splinting because of abdominal inflammation breathing is limited and the lungs function abnormally. These are only a few instances of the functional relationship of the two cavities which may have clinical significance.

There are structural relationships which also are important. The abdominal muscles for instance are innervated by the lower intercostal nerves. Anteriorly the internal mammary vessels anastomosing with the deep epigastrics are closely associated with lymphatic channels which drain abdominal

and thoracic structures. In the retroperitoneal tissues the pathways connecting both cavities are large and numerous. Especially in the lymphatics of the diaphragm is found an intimate relationship for the inferior or subperitoneal network empties partly into supradiaphragmatic nodes and the superior or subpleural network empties partly into intra abdominal nodes. The subpleural and subperitoneal vessels of the diaphragm also intercommunicate freely by means of perforating trunks. It is not surprising that clinical evidence of infections and tumors involving abdomen and thorax together is seen so often.

PERITONEAL REACTIONS

Injury to the peritoneum may be of any character that affects other parts of the body. The commonest are mechanical and chemical the latter including the products of bacteria. The injury to the peritoneum may cause death of tissue or may merely set up the reaction known as the process of inflammation. If there is death of tissue or a break in the continuity of the peritoneum the process of repair will also be initiated.

(a) *Process of Inflammation*—This reaction can be well studied by injecting bacteria or chemicals into the peritoneal cavity of a laboratory animal in amounts that will be irritating but not lethal. Before the injection the peritoneal fluid is clear, viscous and hardly greater in amount than is needed to lubricate the surfaces. It contains usually over 90 per cent large mononuclear cells which are phagocytes. The remainder of the cells are eosinophils, small round cells with occasionally a polymorphonuclear basophil or small mononuclear to be seen. During the first half hour after injection inconstant changes occur. There may be transient appearances of eosinophils or small round cells. Before twenty minutes has passed polymorphonuclear leukocytes begin to appear and within an hour these cells come in a great flood which dominates the cellular elements of the fluid. A differential count at this time will show them to be well over 90 per cent with a tremendous quantitative increase as well. When three or four hours has passed mononuclear cells appear which stain deeply and which are almost surely young macrophages because shortly there-

after the adult macrophages are evident in large numbers. Meanwhile the peritoneal fluid has increased in amount and rapidly become more fibrinous. Clots of fibrin form which contain in their meshes wandering cells and foreign particles or bacteria if these were injected. The fluid is no longer uniform. By this time under favorable circumstances phagocytosis has occurred. The polymorphonuclears the first of the phagocytes to arrive can be seen actively engulfing bacteria or foreign bodies. They soon thereafter begin to disintegrate. The macrophages engulf bacteria and foreign particles and degenerating leukocytes as well. Both kinds of cells obviously perform a useful function and controversy as to which is the more important seems superfluous. As the days pass the degenerated cells and their phagocytosed contents disappear probably becoming dissolved or phagocytosed by fixed tissue cells. New macrophages keep appearing so that at the end of six or seven days the entire process of inflammation has seemingly subsided and the peritoneal fluid has returned to normal.

The periods of time given in the preceding paragraph are subject to wide variations and even the character of the reaction may change. If an overwhelming dose of micro-organisms is injected no wandering cells may appear and the animal may die of septicemia without being able to produce an inflammatory response. Also if a focus of infection is set up within the peritoneal cavity instead of a single injection of an irritant the timing and character of the response varies. But within limits the inflammatory response follows a constant pattern and is not specific for any irritant.

The appearance of wandering cells within the peritoneal fluid means that tissues remote from the peritoneum have been stimulated notably the bone marrow. The serous cells and the all important subserous tissue have also taken part in the reaction. The serous cells may become swollen or may disappear in places if the reaction is severe. The subserous tissues undergo the familiar changes of inflammation of soft parts viz., edema, engorgement of capillaries and production of macrophages from the fixed tissues. In the omentum and elsewhere so-called potential vessels appear i.e. small

vessels that normally do not conduct blood to any extent but do so actively during inflammation. In the fat columns around the vessels of the omentum and mesentery great production of phagocytes occurs. Meanwhile the lymphatics are active in transferring absorbed particles and substances in solution to the lymph nodes which drain the part of the peritoneum which is inflamed. Probably also there is a back and forth movement of lymph within the subserous vessels and a re-routing of lymph through channels which it ordinarily does not take. Thus effect if it does occur is of inestimable importance because it explains well the distribution of infection and of cancer through subperitoneal tissues which is familiar to all surgeons and which sometimes takes place very extensively.

(b) *Process of Repair*.—When peritoneum is divided or dies it undergoes repair in a manner similar to that of serous membranes elsewhere. The process of inflammation is set up in the course of which fibrinous fluid comes from the subserous layers and forms clots within the peritoneal cavity. Wherever the serous cells are injured these clots adhere and where an injured surface comes into contact with another injured surface or even with a previously uninjured one the two surfaces stick together by means of the clot. This is the first stage of adhesion formation. Later if this adhesion persists it may become organized by young connective tissue including blood vessels so that it becomes a living structure a fibrous adhesion and no longer a fibrinous one. Defects in the peritoneum are healed by the same sort of reparative tissue. The serous surface is renewed not by ingrowth of serous cells from the edges as defects in epithelium would be repaired but by metaplasia of the young connective tissue cells which happen to lie on the surface of the reparative tissue. These change from fibroblasts into flattened polygonal cells which are indistinguishable from the original serous cells so that a smooth surface is again formed.

The ultimate fate of adhesions is unpredictable. In general the more intense the inflammatory process the thicker the resulting adhesions. Peritoneal adhesions differ greatly in their capacity for forming adhesions. Some form

them to an extraordinary degree so that for the rest of their lives after an original peritoneal inflammation they are the victims of repeated attacks of symptoms caused by partial or complete intestinal obstruction. In other instances very extensive adhesions will disappear almost entirely in the course of a few months. The factors controlling the formation, disappearance and persistence of adhesions are not understood and attempts to alter their course by placing various substances in the peritoneal cavity have not been generally successful. Fortunately only occasionally do peritoneal adhesions cause symptoms. They are blamed for postoperative symptoms far more often than is justified. The best means of avoiding them include gentle surgical technique, minimal trauma to peritoneal surfaces from drying pads and retractors, adequate drainage of infections, avoidance of vertical incisions which cross many segments of intestine and perhaps making an effort to fasten the omentum into the upper abdomen where it is restricted as to the structures to which it can adhere.

DISEASES OF THE PERITONEUM

1 *Peritonitis*.—Peritonitis means inflammation of the peritoneum not necessarily of bacterial origin. Every time the peritoneal cavity is entered at operation peritonitis follows. The usual cause however of clinically significant peritonitis in human beings is bacteria. Peritonitis is classified according to its extent as generalized diffuse or localized. The localized variety may be in the form of an abscess. Generalized peritonitis practically never occurs as a result of a focus within the peritoneal cavity such as appendicitis because even in fatal cases the process becomes arrested before the entire peritoneal surface is involved. It may be found in peritonitis caused by tubercle bacilli, hemolytic streptococci or pneumococci. Peritonitis is said to be localized when only a small portion of its surface is inflamed such as occurs sometimes in the neighborhood of an inflamed appendix. There is no line of distinction between diffuse and local peritonitis.

Non Bacterial Peritonitis.—Non bacterial peritonitis occurs in human beings when sterile irritating or traumatizing substances

grain entrance into the peritoneal cavity. Common causes are the instruments and gauze introduced at the time of operation body fluids such as bile or stomach contents which have escaped through a ruptured gastric ulcer. These substances may be sterile. Blood can be irritating to peritoneum after it becomes clotted or otherwise altered from its normal state. A ruptured ovarian follicle or cyst may cause sterile peritonitis. In the early stages of acute appendicitis of gangrene of the intestine or of acute mesenteric lymphadenitis there may be an excess of peritoneal fluid which is sterile accompanied by inflammatory changes in the peritoneum. The reaction caused by these irritants is a true peritonitis which is indistinguishable from peritonitis of bacterial origin except that the clinical signs of toxicity are usually less and the local signs of tenderness spasm or rigidity may be milder. However no surgeon is wise enough always to distinguish bacterial peritonitis from aseptic peritonitis with any degree of assurance.

Foreign bodies are nearly all irritating enough to set up some degree of inflammation if left in the peritoneal cavity. A smooth object such as a marble may move about within the cavity for a while but it is usually soon fixed to one site by adhesions which are the result of inflammation. More irritating substances such as a gauze sponge cause far more inflammatory reaction and abundant adhesions which mat together structures about the gauze and actually grow into its meshes. Dust particles in the peritoneal cavity can remain for long periods if they are inert or may be removed by phagocytes or even may form small fibrotic nodules. The symptoms caused by foreign bodies and the reaction around them vary from none to degrees of severity which require operation. If pathogenic bacteria are introduced with the foreign body an infection may follow which will not subside until the foreign body is removed.

Peritonitis Caused by Intestinal Micro-organisms—This is the usual variety of peritonitis and the commonest source is the appendix. The infection is usually caused by two or more varieties of organisms although in the early stages of an infection a single strain may be found.

(c) **CHARACTER OF MICRO-ORGANISMS**—The commonest organisms to be found are in the order of frequency some variety of the group of *E. coli* some strain of non-hemolytic or alpha hemolytic streptococci and *Cl. welchii*. None of these strains is apt to be of high virulence even when grown directly from fatal cases. It takes large doses of any of them to kill laboratory animals or human beings. Probably all of the strains of *Cl. welchii* most of the *E. coli* and some of the streptococci are toxin producers and herein lies their ability to produce fatal infections. Peritonitis may be thought of as a disease caused by great numbers of intestinal organisms of low virulence which produce toxins in a body cavity which has great powers of absorption. It is the toxins and not the bacteremia which is fatal and the complications not the infection itself are the mechanism of death.

(b) **COURSE OF PERITONITIS SPREADING FROM AN INTRAPERITONEAL FOCUS**—One of the most important factors which control the course of an infection in the peritoneum is the speed with which micro-organisms disseminate from the focus. If the invasion of the wall of an appendix by bacteria for example is slow there may be time for an inflammatory reaction to occur always in advance of them. In this way fibrinous exudate may form on the serosal surface of the appendix and the micro-organisms however far they penetrate and cause death of tissue always remain walled off from the free peritoneal cavity by the adhesions which keep forming ahead of them. Such a process may well result in the formation of an abscess in which there may be much pus or sometimes only a little pus surrounded by a massive wall of inflamed hard tissues among which sub-peritoneal fat is apt to play a prominent role. But if instead of slowly penetrating a lesion such as a typhoid ulcer of the ileum suddenly ruptures and the filmy adhesions which covered it are torn apart there is then rapid flooding of the peritoneal cavity of greater or less extent by contaminated fluid and the area of contamination may be extended by gravity motions of the body or peristalsis. A relatively large focus of infection is thus suddenly set up from which absorption occurs over an extensive surface. This focus it is true may become limited by

the formation of adhesions but the chances of controlling the spread of infection and the toxemia are not so good as when the dissemination is slow. In both instances the barrier against continued diffusion of the infection is the adhesions.

After the initial infection whether rapid or slow the peritonitis develops according to the dictates of many factors. There are anatomical arrangements of the intra peritoneal organs and their mesenteries which control to some extent the direction in which infection spreads. A perforating duodenal ulcer for instance tends to force its fluid downward along the right side of the mesentery of the small intestine. Infections in the lower abdomen often point into the pelvis which is one of the customary sites for abscesses. From foci in the upper abdomen and sometimes for some reason also from the appendiceal region abscesses tend to form somewhere in relation to the liver either in it or above it (subphrenic) or below it (subhepatic). When the peritonitis is well controlled the formation of a single abscess near the focus may be all that occurs. In more diffuse processes multiple abscesses often form which may be distinct from each other or may be connected by complicated sinuses. The adhesions determine the limit of the pus in any case. Instead of actual abscess formation large masses of indurated tissues may develop which are impossible to distinguish clinically from abscesses and which may subside spontaneously. Small pockets of pus in these masses may be absorbed. Abscesses or inflamed masses of this kind may lead to fistula formation between various organs or between an organ and the outside of the body. It is important for the surgeon to know the routes of spread in the retroperitoneal tissues when dealing with these complicated chronic infections.

(c) **DIAGNOSIS OF PERITONITIS**—This involves a double duty, namely the determination of whether or not peritonitis is present and the identification of its source or focus. The diagnosis of peritonitis rests somewhat on the history which may be exceedingly varied but nearly always includes abdominal pain. There are no wholly reliable physical findings and the signs vary according to the length of time that the inflammation has been present, its extent, location and other

factors. It is easy to list the physical signs which ought to be present with peritonitis but it is often extremely difficult in examining any given patient to be certain whether those signs are there or not. In the early stages the patient may or may not look acutely ill. The temperature may be anywhere from very high to subnormal. The pulse rate is nearly always elevated. The respiratory rate is variable. The patient may be unwilling to lie with his legs straight out. Nearly always there is abdominal tenderness of greater or less extent and degree. The abdomen usually feels hard for some of its extent and this hardness may be due to spasm of the abdominal muscles or to a mass. It is well for the examiner to bear in mind that he cannot always tell the cause of the resistance to his palpating hand and not to interpret it too lightly. Tenderness or a mass may be revealed better by pelvic than by abdominal examination.

All of these physical findings may be the result of lesions other than peritonitis. Retroperitoneal hemorrhage, renal colic and pleurisy all may be accompanied by spasm or resistance on the part of the abdominal muscles. Even retroperitoneal tumors such as lymphosarcoma or Hodgkins disease may cause signs that are indistinguishable from those of peritonitis. In a nervous or very obese patient it is often difficult for the examiner to be sure of the physical signs. One maneuver which may clarify a confused picture is for the examiner to press with some firmness on the anterior surface of the upper thigh where the patient will usually agree that tenderness is absent. The pressure is then applied at spots successively higher on the thigh until Poupart's ligament is reached. If when the examiner presses on the abdominal side of Poupart's ligament tenderness suddenly is manifest whereas below the ligament it was not present then peritoneal irritation is almost surely present and its cause must be determined. The usual sources of doubt lie in the interpretation of positive findings. The examiner wonders whether the tenderness he elicits is severe enough to be significant or whether the spasm is truly involuntary.

If it is decided that peritonitis is in all probability present the matter of determining its source or focus is a complicated one.

and is best described under the discussion of the various intra abdominal lesions

(d) TREATMENT OF PERITONITIS—The principles of treatment of peritonitis are (1) to prevent and treat the complications (2) to eliminate the focus of infection (3) to combat the micro organisms directly with drugs whenever possible and (4) to drain abscesses as soon as feasible

(1) The complications are often numerous and usually play a major role in prolonging the disease or causing a fatal outcome. Pneumonia usually occurs in severe cases. Toxicity may be the chief cause of the rapid pulse or even of cardiac failure. Junctice anuria, ileus and psychic changes. Ileus is often produced wholly or in part by organic obstruction which is especially apt to happen where intestinal coils come into contact with inflamed tissues and themselves become kinked or edematous. The organic factor should always be sought if ileus is present even in the presence of a silent abdomen for paralytic and mechanical ileus may be interdependent. The adjustment of fluid, chemical and cellular elements in the blood stream and thereby in the tissues is essential.

(2) Elimination or at least drainage of the focus of infection is as important in peritonitis as in any other infection. There are times when it may be wise because of the general condition of the patient to postpone this step, hoping that adhesions will wall the focus off but the principle of earliest possible removal of the focus remains fundamental. It is in this matter that the technical skill of the surgeon may determine whether the removal of the focus in any given case is wise. An inflamed appendix removed in a blundering manner might perhaps better have been left to nature to combat.

(3) Little progress had been made in destroying the micro organisms directly until the advent of sulfanilamide. Sera were not successfully employed in spite of the vogue they had at one time in Germany. Other bactericidal products were not beneficial. The sulfonamide group however can be shown experimentally to be effective especially in the early stages. Once the micro organisms become entrenched in dead tissue and pus the effect of the drugs is lessened. They are never more than an adjunct in

the treatment but the clinical evidence is that they are often useful. Attempts have been made to increase the resistance of the peritoneum to intestinal bacteria by means of intraperitoneal injections of vaccines and other substances before abdominal operations. These would have no effect if injected after the infection had taken place but might produce a local immunity which could prevent an infection from starting. The evidence is that a certain small degree of non specific immunity can be produced but it is of no practical value.

(4) There are certain aspects of peritoneal abscesses that are distinctive and there is not usually need for hasty action in draining them. The surgeon often does well to wait till the abscess points very clearly before attempting incision. The reason for this is appreciated only by one who has tried to find in the peritoneal cavity pus whose whereabouts was not obvious. In the mass of inflamed tissues which can form within the abdomen adhesions may conceal identity of structures, planes of cleavage are indistinguishable, the operative field is obscured by uncontrollable oozing and guides and landmarks vanish. It is extremely easy to enter the lumen of the intestine or to cause bleeding from large vessels which in the friable inflamed tissues is hard to control. Great damage can be done and the pus perhaps not found. Peritoneal abscesses in the pelvis will often rupture spontaneously into the rectum or vagina if allowed to do so. It seems to be true that abscesses in other parts of the peritoneum also sometimes disappear perhaps as the result of rupture into a viscus or perhaps by absorption. It is hard to be sure how often this happens because the signs of peritoneal abscess can be mimicked by other conditions. Altogether the diagnosis and details of treatment of peritoneal abscess sometimes require a high degree of surgical ability and training.

(e) PERITONEAL DRAINAGE—When a peritoneal abscess is opened and also under certain other circumstances it is desirable to institute drainage. The matter of when and how to drain is a controversial one but there are fundamental principles for guidance. The purpose of a drain anywhere in the body is to keep the superficial layers of the wound open until the dead tissue and discharges in

the depths have separated and came away and the wound is ready to fill in with healthy tissue from the bottom. It is impossible to drain more than a small part of the peritoneal cavity at once. This is true not only because of the manifold crevices and pockets into which the cavity is divided but also because of the reaction of the peritoneum to a drain. The drain is always a foreign body and as such causes the peritoneum with which it is in contact to become inflamed and to discharge its fibrinous exudate. This exudate clots wherever the flow of fluid is not active thus forming adhesions about the drain which wall it off. Drains therefore cannot be effective for more than a few centimeters from their location. The importance of accurate placement of drains is obvious.

There are four principal reasons for draining the peritoneal cavity:

(1) The presence of gross amounts of dead tissue associated with micro-organisms. There is always dead tissue left behind after operations due to clamping and ligating of cut vessels injury by instruments etc., but these minute amounts may be safely ignored. Gross amounts of dead tissue in the presence of infection or severe contamination should be drained.

(2) Insecure closure of a hollow viscus. The emphasis here is on the word 'insecure' and that is always a matter to be determined by the surgeon's judgment and experience. Sometimes closure of a hollow viscus must be done by approximation of inflamed tissue and the surgeon hopes that his sutures will remain intact but fears that they may not. Or the surgeon may believe that he has left too much tension on his line of suture or that the blood supply of the tissues he has approximated is not excellent or that undue pressure may arise within the viscus. Under such circumstances it is better to have a drain accurately placed to the point of danger than to risk escape of the contents of the viscus into the peritoneal cavity with no way prepared to the outside. An example of this is the stump of the cecic duct remaining after cholecystectomy which however securely ligated may open and allow bile to discharge.

(3) Uncontrolled bleeding. Raw surfaces may be left after operation which ooze in a

manner difficult to control. It is better to conduct the discharge outside the peritoneal cavity.

(4) The presence of exposed retroperitoneal tissue plus contamination. The reason for draining in this circumstance is that the tissues beneath the peritoneal cells are far less resistant to invasion by micro-organisms than are intact peritoneal surfaces.

The foregoing reasons are specific and there is usually little doubt in the operator's mind whether one of the conditions mentioned is present or is not. It is to be noted that contamination alone is not a reason for draining. The peritoneum can take care of a vast amount of contamination provided it is intact. No contamination of an area that is small enough to be controlled by a drain is to be greatly feared. Extensive contamination is dangerous but extensive areas can not be drained. When however contamination is associated with dead tissue or raw surfaces accurately placed drains are usually needed.

Much can be done to reduce contamination before the abdomen is closed. It is good practice to take time to aspirate accurately and carefully pockets in the peritoneum where fluid or foreign particles may collect. The pelvis the lumbar gutters and the recesses about the liver and kidneys often contain fluid. In this way the quantity of micro-organisms in these areas may be so reduced that the intact peritoneum can dispose of the remainder. Attempts to irrigate the peritoneum are usually unsuccessful but an irrigating tube with a suction tip attached to it may at times be useful. It is not yet clearly established whether placing drains such as sulfonamides in the peritoneal cavity has any advantage over giving them by other routes.

The kind of drainage that is instituted must be fitted to the need of the case. If drainage is needed at all it is usually best to err on the side of providing excessive avenues of escape for the fluid. Where the fluid is expected to be small in amount and not too thick rubber tissues may suffice as they allow exudate to escape around them. They have the advantage of being soft and adaptable but the disadvantage of being difficult to adjust later except to shorten. If more than a little discharge is expected one or

more soft, black rubber tubes may be preferable, as they maintain a lumen if kept clean and can be slid back and forth to make sure that they are free. It is the sealing off of drains in the depths by fibrin which leads

to infected or badly contaminated cases, it may be wise to place the drains to the site chosen and then close only the peritoneum (with posterior sheath if the rectus is involved) for the remainder of the wound. A china silk

Fig 522—A man had a laterocolic appendiceal abscess with a cecum which lay in the right upper quadrant. A transverse incision was made over the mass, which lay in the flank about the level of the umbilicus. In order to gain working room the incision was carried medially across most of the right rectus. The large appendix was removed leaving the wall of the abscess behind and some retroperitoneal tissue which was denuded of peritoneum. The medial portion of the wound, i.e., that part which involved the rectus, was closed to prevent evisceration by approximating the posterior sheath and the peritoneum, but in order to minimize the danger of infection of the abdominal wall, no other sutures were taken in the wound. A sheet of china silk was used to hold apart the subcutaneous tissues medially. The abscess was drained by means of a double rubber tube. The principles are to supply free drainage to the area where the dead tissue and contaminated exposed retroperitoneal tissue are found, to prevent evisceration and to avoid so far as possible locking up micro-organisms in the abdominal wall. The area of peritoneum contaminated during the operation is too extensive to drain easily, and in any case there is no need to drain it, as it is intact. A, Showing location of the cross sections B, Cross section at A-B C, Cross section at C-D

to many disasters, and a drain that can be lifted off the bottom of its tract and then slid back into place has a great advantage. Often the problem arises of how to close part of an abdominal wound and at the same time drain through it. In dealing with in-

tampon may be loosely placed down to the closed sheath. In wounds of even great size, it may be best not to close the peritoneum at all but to place a silk tampon, filled with cigaret drains, firmly through the peritoneal layer, so as to wall off the viscera from the

rubber tube drains and at the same time prevent evisceration. It is a mistake to close tightly about a drain. The aim is rather to avoid closing wounds as far as possible in the presence of infection or expected infection. Drainage must also be free. A drain placed down to a leaking viscus or other focus even though it allows escape of some of the fluid may not prevent dissemination of the remainder throughout the peritoneal

commonest focus. It often appears as multiple, small gray pearly tubercles which slune through the mesothelial layer and feel like small shot placed in the subperitoneal tissue. This form of the disease is diffuse. It may also occur as localized involvement of one organ, where it may cause distortion due to scarring and contraction. In the large intestine for instance it may closely resemble carcinoma. It may go on to large areas of

Fig 523—A transverse incision was made dividing the left rectus low down and extending upward and outward through the lateral abdominal muscles and the peritoneum under them. The sigmoid colon was resected because of severe recurring diverticulitis. The infection was limited to that segment of the bowel. Much of the sigmoid and the upper part of the rectum was removed. The rectal stump was turned in a fistula between the bladder and the sigmoid was interrupted and the opening in the wall of the bladder was closed. An abscess was found in the cul-de-sac. The dissection was difficult. retroperitoneal tissue spaces were of necessity opened up over a large area and there was much contamination of the lower peritoneal cavity. The abscess wall deep in the pelvis was left in. The wound was treated as follows. The proximal end of the divided sigmoid was brought out through the lateral angle of the wound as a permanent terminal colostomy. The wound was closed in the peritoneal layer only in order to avoid infection of the abdominal wall between the colostomy and the lateral margin of the rectus muscle. In the medial portion of the wound a double soft rubber tube drain was placed down to the abscess in the pelvis. Cephalad to this was placed a tampon of china silk which contained numerous soft cigaret drains. The tampon was placed deep into the pelvis so as to hold back the intestines from eviscerating, and from coming in contact with the tube drain. Within forty-eight hours as the intestines became fixed to each other and to the peritoneum near the wound margin the cigaret drains were started out of the tampon. The tube drains meanwhile were moved slightly each day and irrigated. The china silk was removed at the end of a week, and the tubes were allowed to shorten themselves slowly.

cavity with fatal results. The safeguard is a means of exit to the surface that is sufficiently wide accurately placed and direct.

Special Types of Peritonitis—(a) **TUBERCULOUS PERITONITIS**—This disease occurs more often in women than in men and in the young than in the old. It may occur as part of a miliary dissemination or may originate as it frequently does in some intra-peritoneal organ. The fallopian tubes are its

commonest focus. It often appears as multiple, small gray pearly tubercles which slune through the mesothelial layer and feel like small shot placed in the subperitoneal tissue. This form of the disease is diffuse. It may also occur as localized involvement of one organ, where it may cause distortion due to scarring and contraction. In the large intestine for instance it may closely resemble carcinoma. It may go on to large areas of

cavisation with ulcer formation and fistulas. In all of the forms fluid is characteristically present, either as diffuse ascites or in restricted pockets. The onset of the infection may be violent enough to suggest an acute suppurative peritonitis or may be so gradual as to suggest typhoid fever. The symptoms are variable but usually include more or less fever, malaise, loss of weight, abdominal discomfort and distention. In the diffuse type

the presence of fluid is demonstrable. The umbilicus is apt to be everted. It is a standard statement in medical literature that the abdomen has a doughy feel, but this is not literally true. The abdomen is not plastic but usually softly distended and not very tender. The treatment consists of general supportive measures, simple opening of the abdomen with aspiration of the fluid if the process is diffuse or often removal of a diseased focus if one is present. If the process is not associated with extensive tuberculosis elsewhere in the body, the prognosis is not bad.

(b) **GNOROCOCCAL PERITONITIS**—This comes from infection of the female genitalia. It is rarely fatal. It is important because it

mild degree of rigidity may characterize the illness. If a young girl has evidence of diffuse peritonitis without localizing signs over the appendix, a high leucocytosis and evidence of great prostration, the diagnosis of pneumococcal peritonitis must be strongly considered. Before the advent of penicillin and the sulfonamides, the disease was usually fatal, although it sometimes went on to abscess formation with or without recovery. Now the prognosis in cases recognized in time is greatly improved.

(d) **PERITONITIS CAUSED BY HEMOLYTIC STREPTOCOCCI**—In certain cases of widely disseminated even generalized peritonitis, hemolytic streptococci are found in pure culture. This infection may follow a strep-

Fig. 324—A Subdiaphragmatic abscess extending from a paracolic abscess. B It is drained by both a gauze pad and a rubber drain.

resembles diffuse peritonitis of intestinal origin, especially that following appendicitis. If the diagnosis is not perfectly clear, it is better to explore the right lower quadrant and usually remove the appendix than to risk the dangers of postponed operation. The erythrocyte sedimentation rate is usually higher in gonococcal peritonitis than it is in appendicitis, but often a differential diagnosis is impossible. Sulfa drugs are usually effective in controlling the infection.

(c) **PNEUMOCOCCAL PERITONITIS**—This may occur secondarily to pneumococcal infections outside of the peritoneal cavity or may follow infection of the fallopian tubes. It occurs chiefly in girls under ten years of age. Diarrhea, distention and a surprisingly

toxic lesion elsewhere in the body, as for instance acute pharyngitis. The symptoms and signs are those of a severe infection with evidence of peritonitis. The treatment is chiefly the use of the sulfonamides or penicillin, proper handling of any discoverable focus, drainage of any abscess that may form and perhaps aspiration of the peritoneal fluid.

(e) **OTHER TYPES**—Evidence of peritoneal inflammation occurs in relation to acute rheumatic fever. The pathologic processes involved are not well known. Occasional cases are reported of peritoneal infection with microorganisms other than those previously

* Hertzler in *Clinicopathology Textbook of Surgery*, ed. 5, p. 1377.

described, many of these invaders probably coming from the intestinal tract. Actinomyces may cause peritonitis, and diffuse infections have been described in relation to lymphogranuloma inguinale and brucellosis. Almost any type of pathogen may be recovered from the peritoneal cavity as medical rarities.

Any type of peritonitis may become chronic. In these cases, the peritoneum becomes thickened, and adhesions are present. Chalk-like, hyaline deposits have been described, as in peritonitis arenosa. This condition is rare. When inflammation has lasted several days, so-called peritoneal irritation

myxoma or pseudomyxoma, sometimes called hydrops spermis. In the ovary, pseudomucinous cysts are the probable point of origin. In either case, the mucoid material escapes from the appendix or ovary and is discharged with bits of epithelial lining into the peritoneal cavity. These fragments are implanted into distant parts of the peritoneum or its organs and continue secreting so that lakes of thick jelly are formed. The jelly and the epithelium act as irritants, so that there is a reaction on the part of the peritoneum, with some inflammatory exudate and the formation of adhesions. The

Fig. 525.—Subdiaphragmatic abscess which is not accessible from the abdominal wall. A, a preparatory pack is placed in the thoracic cavity to secure a channel to the diaphragm. B, the abscess is drained secondarily.*

cells may be found, which are groups of large mononuclear cells, probably phagocytic, which project from the peritoneal surface. An excess of clear or slightly cloudy sterile peritoneal fluid may be present in chronic peritonitis. It is apt to contain an unusually large number of macrophages. This may be found for instance in the free peritoneal cavity in the vicinity of an abscess.

2. *Pseudomyxoma Peritonei*.—This unusual condition, more casually known as "jelly-belly," arises in most if not all cases from a lesion in the appendix or ovary. In the appendix the source is probably a

ultimate result is masses of adhesions and gelatinous exudate which give rise to a variety of symptoms, such as distention, abdominal pains and changes in bowel habit. The treatment is removal of the focus, following which the implanted masses sometimes disappear. The prognosis for a long life is not necessarily altered by the condition. It is to be distinguished from colloid carcinoma with metastases, which can give a picture which is similar grossly, but the differential diagnosis can be made by the char-

* Hertzler, in Christopher Textbook of Surgery, ed 3 p 1078

acter of the cells present as the lining cells in pseudomyxoma do not resemble malignant cells

3 Tumors and Cysts—Nearly all tumors of the peritoneum are metastatic. There is only one form of malignant tumor of peritoneal origin that is generally recognized and that is the so called mesothelioma. Other tumors arise in the retroperitoneal layers both benign and malignant similar to tumors of soft connective tissue elsewhere

in the body with which they are best classified. Cysts lined by cells resembling peritoneal cells are found frequently about the pelvic organs of the female. Subserous cysts occur having their origin probably in fetal remnants of the genitourinary system or in lymphatic channels. Cysts also occur as a result of infestation with animal parasites notably the echinococcus. Epithelial cysts such as dermoids are not truly of peritoneal origin.

HAROLD D. HARVEY

XXVII. THE STOMACH AND DUODENUM

CONGENITAL MALFORMATIONS OF THE STOMACH

Congenital malformations occur less frequently in the stomach than in any other part of the gastrointestinal tract. Cases have been reported in which the stomach was found in the thorax as a result of a defect in the diaphragm either at the esophageal opening or in the right or left leaf. In these cases the stomach was quite normal except for its position. Other malformations which have been reported are atresia at the cardia or pylorus, congenital hour glass stomach and aberrant pancreatic tissue located at the pylorus. These conditions occur so infrequently however that for all practical purposes they may be disregarded. By far the most common congenital malformation of the stomach is congenital hypertrophic pyloric stenosis which will be considered in detail.

CONGENITAL HYPERTROPHIC PYLORIC STENOSIS

Congenital hypertrophic pyloric stenosis was first described as a clinical entity in 1777 when George Armstrong reported a case in a three week old infant. In 1788 *Herakleus Bertridley* reported the autopsy findings in a case. Williamson of London reported a typical case in a male infant in 1841. In 1842 Simeon Davosky was the first to note the projectile vomiting; he reported the first case in Germany, in that year. In 1879 Landerer first used the name congenital hypertrophic pyloric stenosis. In 1887 Hirschsprung called attention to the condition as being peculiar to infancy. In 1896 Finkelstein mentioned a palpable tumor for the first time. The greatest progress in the study and treatment of this condition has been made since the advent of the Fredet Rammstedt operation in 1912.

Occurrence—The incidence of pyloric stenosis is not accurately known but the condition occurs frequently enough so that the practitioner should have a clear understanding of the clinical picture and the

proper treatment. It occurs about seven times more often in male than in female infants and frequently in the first child of a family. It may occur in more than one member of a family. In one family of 12 children the first, fifth and ninth boys had pyloric stenosis. A girl whose father had been operated on in infancy for pyloric stenosis was operated on recently for the same condition.

Anatomy—The normal pyloric canal of an infant measures about 1.5 cm. in length. The pylorus projects into the duodenum as the cervix does into the vagina. In pyloric stenosis the entire pylorus is converted into a tumor because of hypertrophy of the circular muscle layer. All other elements of the pylorus are normal.

Etiology—The etiology of this condition is still unknown. Many theories have been advanced but none has been able to explain either the great muscular hypertrophy which is present at birth and which disappears after the Fredet Rammstedt operation or the occasional spontaneous cure without operation. It has been definitely proved that the tumor is present at birth from the examination of premature babies with well defined tumors but the symptoms do not usually become evident before the second week of life at which time the pylorospasm associated with the tumor begins. In all cases the hypertrophy precedes the spasm but it is the combination of the two that causes the pyloric obstruction. The severity of the symptoms is due to the variation in degree of the spasm rather than to the size of the tumor.

Pathology—In a well marked case the pylorus is characteristic. It appears as a firm white fusiform mass about 2.5 cm. long with a consistency about like that of cartilage. The tumor is freely movable, and the peritoneal coat is smooth and glistening. The lumen of the pylorus is probably never completely closed but it may be only large enough to admit a probe. On section the circular muscle coat is often seen to be five times its usual thickness but all other structures appear normal. As a result of the ob-

struction the stomach is both hypertrophied and dilated often to three or four times its normal size and in some cases its outline may be seen through the abdominal wall.

Clinical Picture—The clinical picture of pyloric stenosis is strikingly uniform. Vomiting which is always the first symptom begins in most cases between the second and the fifth week of life. Up to this time the infant has appeared quite normal. This vomiting which begins as a regurgitation soon becomes projectile and the quantity of vomitus is so great that it leaves no doubt that gastric retention exists. The vomitus never contains bile but may contain blood. The vomiting is so forceful that the vomitus may be projected several feet. It may occur directly after each feeding or if less frequent

has been palpated. The pyloric tumor in the right upper quadrant of the abdomen is the one sign that is pathognomonic of pyloric stenosis; it is found in no other condition and its presence therefore establishes the diagnosis. It may be felt in every case if the examination is properly made with the stomach empty and the child relaxed. Occasionally it is necessary to examine a child more than once to feel the tumor but with greater experience the physician rarely needs to make more than one abdominal examination. No patient should be operated on until the tumor has been felt.

The tumor is best described as feeling like a small olive but it varies considerably in size depending on whether or not the pylorus is contracted during the examina-

Fig. 526—*a* The stomach in a case of pyloric stenosis. *b* A normal stomach from an infant of the same age.

the amount vomited which represents the entire stomach content may be equal in volume to that of several feedings. Since the child is losing all his nourishment by vomiting he loses weight rapidly and soon becomes dehydrated and wasted. For the same reason he is constipated and passes only small amounts of urine.

Gastric peristaltic waves are visible in all cases. These vary considerably in intensity, being most striking in a late case. They are seen best when the stomach is full, starting at the left costal margin and passing to the right. More than one wave may be present at a time. While peristaltic waves are found in other conditions in infancy and therefore cannot be considered pathognomonic of pyloric stenosis, they are often helpful in establishing the diagnosis before the tumor

is felt. The tumor may lie anywhere in the right upper quadrant of the abdomen; if it lies under the rectus muscle it may easily be confused with the linea transversa. It is best felt when the stomach is empty and a clue to its location may be obtained by watching the point where the peristaltic wave ends. If pressure is made on the fundus of the stomach with the left hand while one palpates for the tumor with the right hand the tumor may be brought out from behind the rectus muscle or down from beneath the liver to a point where it is more easily felt.

Diagnosis—Since these cases run quite true to form an intelligently taken history and the recognition of peristaltic waves are helpful but the diagnosis depends entirely on feeling the tumor.

The diagnosis may be made roentgeno-

graphically, but in the writer's experience this method has been purposely avoided both because the diagnosis may be made without it and because the barium may increase the postoperative discomfort.

Pyloric stenosis must be differentiated from duodenal stenosis which is due either to congenital atresia or to a band. In pyloric stenosis the symptoms do not become evident before the second week, while in duo-

denal stenosis the symptoms are not severe and the infant is almost three months of age. With the present low post-operative mortality, of less than 1 per cent, it seems unnecessary to subject a baby to three months of vomiting and refeeding, as required by medical treatment. A baby, successfully operated on, is perfectly normal and able to tolerate a generous formula two weeks after operation. From an economic

denal stenosis they usually date from birth. In pyloric stenosis the vomiting is projectile, and the vomitus never contains bile; while in duodenal stenosis the vomiting is not projectile, and the vomitus may contain bile. The tumor, of course, establishes the diagnosis of pyloric stenosis.

Treatment.—After the tumor has been felt, the infant should be operated on as soon as he has been put in condition to withstand operation. The only exception to this rule

standpoint alone, surgical treatment is better than medical treatment, which must of necessity be prolonged.

Preoperative Preparation.—Preoperative preparation has probably been the most important factor in reducing the mortality to its present level (1 death in 400 cases). A few years ago these patients were operated on as for an emergency, with a high mortality as the result. Many babies died of shock because their condition was too poor to with-

struction the stomach is both hypertrophied and dilated often to three or four times its normal size and in some cases its outline may be seen through the abdominal wall.

Clinical Picture—The clinical picture of pyloric stenosis is strikingly uniform. Vomiting which is always the first symptom begins in most cases between the second and the fifth week of life. denal stenosis they usually date from birth. In pyloric stenosis the vomiting is projectile, and the vomitus never contains bile, while in duodenal stenosis the vomiting is not projectile, and the vomitus may contain bile. The tumor, of course, establishes the diagnosis of pyloric stenosis.

Treatment.—After the tumor has been felt, the infant should be operated on as soon as he has been put in condition to withstand operation. The only exception to this rule

standpoint alone, surgical treatment is better than medical treatment, which must of necessity be prolonged.

Preoperative Preparation.—Preoperative preparation has probably been the most important factor in reducing the mortality to its present level (1 death in 400 cases). A few years ago these patients were operated on as for an emergency, with a high mortality as the result. Many babies died of shock because their condition was too poor to with-

stand any operation. At present the amount of vomiting and the kind of formula the baby has been receiving are disregarded and efforts are immediately made to overcome the dehydration. Hypodermoclysis of 100 cc of saline and glucose solution twice daily for two or three days is given until the fluid balance has been reestablished. If the infant's condition is desperate he may first be given either an infusion of 10 per cent glucose or a blood transfusion using 20 cc of whole blood for each kilogram of body weight. One or 1½ ounces of 5 per cent glucose solution which is often retained better than a formula of milk is given every two hours before operation.

After two or three days of this treatment there is a striking improvement in the baby's condition with the converting of a baby who might have been considered the poorest possible risk into one well able to withstand an operation. When dehydration is completely overcome the child is operated on the Fredet Rammstedt operation being used in all cases. Ether (open cone) is always used except in cases of infection of the respiratory tract when novocain is used. Ether given with an open cone is so well tolerated that a respiratory infection practically never occurs after operation.

Operation.—A right rectus incision 5 cm. long is made high enough to overlap completely the right lobe of the liver which acts as a buffer and prevents postoperative rupture of the incision in a poorly nourished infant. The right lobe of the liver is retracted upward and the pylorus is delivered into the wound. While the tumor is held between the thumb and the index finger of the left hand an incision is made over its entire length in the least vascular area cutting through the peritoneum and just starting the circular muscle. The cut muscle edges are then separated by inserting a straight mosquito clamp in the stomach end of the incision and spreading it until the mucosa completely fills the incision. Great care must be exercised in separating the muscle for fear of breaking into the duodenum since the change from the thick pyloric tumor to the thin walled duodenum is rather abrupt. The tumor is dropped back and watched for a moment or so to be sure that there is no bleeding from the cut surfaces. If there is much bleeding

the vessel may be ligated some distance from the cut muscle edge with a suture of fine black silk. The abdomen is then closed in layers using black silk (c) throughout.

Postoperative Care.—After operation the infant should be kept in a room with a constant temperature, completely isolated from other patients. Great care must be exercised in the postoperative feeding as in many cases because of the use of a variety of formulas before operation the infant has a low food tolerance. For the first five days breast milk is given with a medicine dropper without picking up the baby. If the baby is to nurse he is allowed to do so once on the fifth day twice on the sixth day etc. until he is completely breast fed. If he is to have a formula evaporated milk is well tolerated. This formula is given once on the fifth day, and if it is well tolerated it may be rapidly increased until the caloric requirements are met. Hypodermoclysis of glucose and saline solution is given daily on the first three days after operation. Skin sutures are removed on the fifth day.

It is unusual to have any but the smoothest convalescence. If a complete operation has been done the baby should not vomit after operation. If vomiting does occur it usually means that the stomach has not been emptied in the operating room. The passage of a stomach tube will produce an immediate response. In most cases there is a gain in weight before discharge on the twelfth day and in a month the condition is the same as it would have been had pyloric stenosis not occurred. The Fredet Rammstedt operation gives a permanent cure as the pylorus has been found to be normal in patients operated on later for other conditions. In contrast to this the pyloric tumor has been found years later to be exactly as it was in infancy if gastroenterostomy was done.

FOREIGN BODIES IN THE STOMACH

Etiology and Varieties—1 Swallowed (a) by inadvertence coins pins marbles buttons broken thermometers false teeth tooth brushes fragments of eating and culinary utensils pencil ends ticks nails dental and surgical material and tools food boluses fish bones (b) by intent nails tools wire twine glass etc by sword swallowers exhibitionists idiots and hysterical and demented persons Paretics may ingest objects large enough to result in strangulation Thieves sometimes swallow coins valuables and legal evidence Suicide is attempted by swallowing glass ticks etc Bezoars may be made up of plant fibers hairs or persimmon seeds or they may accumulate following the repeated ingestion of shellac furniture polish or other solid residues in alcoholic suspension Bezoars may tampon the pylorus or the whole stomach 2 By penetration of the abdominal wall bullets shell fragments and missiles glass knife blades and other penetrating articles surgical drainage tubes (glass rubber and metal usually introduced through a fistula) Murphy buttons overlooked surgical instruments and dressings 3 Of endogenous origin parasites (e g ascaris and taenia) gallstones or bone sequestra ulcerating into the stomach loosened fragments of tumors protracted gastrotomy catheters and Levine and Abbott Miller suction tubes that have been bitten through or otherwise broken or spontaneously knotted in situ

Symptoms and Complications—The gastric mucosa is insensitive to foreign bodies Such symptoms as may arise are due to complications such as pyloric or intestinal obstruction ulceration hemorrhage phlegmons of the stomach or intestines perforative peritonitis or abscess formation internal fistulas permanent retention (bezoars large objects) of non passable material producing chronic catarrh and ulceration or forming granulations or inflammatory masses obstructing or narrowing the lumen and the wandering of foreign bodies beyond the stomach and intestinal tract into the vagina bladder rectum or abdominal wall

Diagnosis—An accurate anamnesis is indispensable but is often misleading Pins coins and other objects can disappear from the hands or even the mouth of a baby idiot demented or normal adult without being swallowed Even bullets may be vomited or passed in the stool unobserved Examination by means of x rays both fluoroscopic and with films is indispensable but for the visualization of radiolucent objects whether in the stomach or in the bowel a contrast medium must be used A gastroscope is occasionally useful

Treatment—The non surgical treatment in cases of the swallowing of the smaller foreign bodies such as coins pins buttons and the like consists in attempting to have the object carried through the canal by bulky soft food ingested in quantity such as Billroth's potato puree well cooked spinach cabbage vegetables mineral oil or rye agar bread in quantity etc Contra indications are symptoms of inflammation ulceration penetration or obstruction The surgical treatment is required when the swallowed object is impressably large is long retained or is producing symptoms or complications Gastroscopic removal is occasionally feasible in skilled hands Gastrotomy is the usual operative procedure There is preliminary cleansing of the stomach by lavage and emptying of the fluid by aspiration A longitudinal incision in the stomach is made halfway between the greater and lesser curvatures The abdominal cavity must be well protected from soiling by careful isolation with gauze packs and any remaining stomach contents must be aspirated The cut should be no longer than needed to permit

removal of the foreign body which previously should be located by palpation or diaphanoscopy of the stomach. Removal with instruments avoids the soiling of the hands and of the wound.

ACUTE PHLEGMONOUS GASTRITIS

(*Acute Suppurative Cellulitis of the Stomach Gastric Erysipelas*)

Definition—A phlegmon (fortunately rare) beginning usually in the gastric mucosa extending rapidly to the submucosa and to all layers of the stomach and as a rule terminating fatally from abscess formation peritonitis and other septic complications.

Etiology—Predisposed are the middle aged males (80 per cent) of the poor classes 25 per cent being habitual users of alcohol. The portals of entry through the mucosa may be furnished by superficial erosions in chronic gastritis achylia and corrosive poisoning by ulcer and ulcerating neoplasms by gastric wounds and operations. The causative organisms may be introduced by the swallowing of pus of buccal peridental tonsillar or nasal origin or via the blood stream (pyemia osteomyelitis endocarditis).

Streptococci are the organisms most frequently found staphylococci and *B. coli* are less often found. In the normal stomach streptococci and *B. coli* rapidly lose their pathogenicity in the presence of free hydrochloric acid. Dogs suffer no ill effects from a diet of streptococci and glass splinters but phlegmonous gastritis develops when the mucosa is damaged with alcohol and streptococci are subsequently fed (Doehle).

Pathology—The gastric wall infiltrated with pus cells and inflammatory edema may be an inch thick. The swollen mucosa is thrown into thick folds and tumefactions. The submucosa shows the earliest and most intense phlegmonous changes but all layers subsequently become involved and may become indistinguishable in the general cellular infiltration and glassy diffuse edema.

There are scattered abscesses and necrotic spots of varying size and number. The surface of the stomach is covered with fibrin or pus and is more or less adherent to surrounding structures. The phlegmon usually but not always stops rather sharply at the pyloric ring and at the esophageal hiatus. Occasionally the duodenum is involved and less often the esophagus.

Suppurative peritonitis is present in 30 per cent of cases. Other complications are perigastric abscess subdiaphragmatic abscess acute suppurative pericarditis and pleurisy septicemia and pyemia.

Varieties—1 Diffuse extensive phlegmon with early death from toxemia and septicemia or later death from abscess formation peritonitis or pyemia. 2 Local phlegmon with localized abscess which may heal spontaneously or after surgical drainage or resection. 3 Subacute phlegmon with less necrosis and suppuration and a milder course healing with more or less extensive scarring of the gastric wall or developing into a limitis plastica often with extensive adhesions to surrounding structures.

Symptoms—The onset is abrupt and violent. Persistent vomiting may be the chief feature with excessive thirst severe and continuous epigastric pain and tenderness. There may be increased resistance to palpation or a palpable tender mass may be found in the epigastrium. Diffuse abdominal tenderness and rigidity with rebound phenomenon and absence of peristaltic sounds indicate complicating peritonitis. In one patient a peritoneal friction rub was heard above and to the left of the navel synchronous with diaphragmatic movements and so constant as to be demonstrated to an entire class. The temperature ranges from 100° to 105° F. Chills may occur at the onset or when pyemia develops. The presence and persistence of pus in the vomitus or aspirated gastric contents usually with blood and occasionally with necrotic fragments of mucosa is very suggestive. The pyloric phlegmon often produces complete pyloric stenosis which can be shown fluoroscopically with a little barium administered orally.

Diagnosis—These cases are usually not diagnosed *intra vitam* unless exploratory laparotomy is performed. Perforated peptic

ulcer acute pancreatitis or acute suppurative cholecystitis is the usual diagnosis made. Suggestive of gastric phlegmon are the onset with chills and septic fever, severe acute pyloric obstruction, pain, tenderness and increased resistance to palpation localized to the epigastrium, pus and necrotic tissue in the vomitus of a middle-aged man suffering from chronic alcoholic gastritis, a chronic ulcer, carcinoma or a recent gastric operation.

An acute suppurative phlegmonous duodenitis is much rarer and an independent lesion and presents a different clinical picture from phlegmonous gastritis because of the inflammatory blocking of the papilla of Vater with obstructive jaundice and absence of the pancreatic ferments in the stools.

Prognosis.—The extent and virulence of the process rather than the therapy practiced determine the outcome. The acute diffuse form is almost invariably fatal whether treated by total resection, extensive tamponing or drainage. The localized and subacute forms are more likely to respond to drainage or excision. The cases in which treatment by excision is successful are likely to be diagnosed as infected neoplasm both before and at operation, their true character being discovered only upon study in the pathologic laboratory.

Treatment.—The excessive vomiting may be controlled by use of a Levine tube and the thirst by the administration of saline solution subcutaneously, intravenously or by proctoclysis. Since both these symptoms are usually due to pyloric obstruction, jejunostomy may be considered but seems scarcely advisable in the occasional cases in which the outcome is a matter of only a few days. An indication for gastrostomy seems questionable although a few patients have recovered following it. Probably the gastrostomized patients have recovered in spite of the operation rather than because of it. The incision and drainage of a well localized mural abscess or a perigastric abscess is distinctly helpful and essential but extensive tamponing of the whole stomach and lesser peritoneal cavity seems more provocative of peritonitis than prophylactic Sulfonamides should be administered either by mouth or by vein or by both method. No penicillin may be tried.

GASTRIC HEMORRHAGE

(Gastrorrhagia, Gastrorrhæxis)

Definition.—Gastric bleeding must not be confused with vomiting of blood (hematemesis) or passing of bloody stools (melena) whether occurring with or without the other signs of internal hemorrhage. These are symptoms of gastric hemorrhage but they are also symptoms of bleeding from other points along the alimentary tract and even the respiratory passages when blood that has been coughed up is swallowed.

Etiology.—The surgeon is chiefly concerned with hemorrhages so massive prolonged or frequently recurring and so unyielding to the usual medical therapy that death appears to impend unless the bleeding is quickly controlled by direct surgical attack on the bleeding point. Erosions and peptic ulcers either acute or chronic are the usual source of the bleeding. Extensive parenchymatous hemorrhages by diapedesis such as are seen with the blood dyscrasias and which infiltrate the entire wall of the stomach are not amenable to surgical relief and are best treated conservatively. Serious bleeding may occur from gastric neoplasms and from dilated veins in the lower esophagus and cardia particularly in cirrhosis of the liver but is less frequent and much less amenable to surgical control than the commoner bleeding from peptic ulcers and erosions. Particularly fatal are the deeply penetrating ulcers of the posterior wall of the duodenum which involve the head of the pancreas because of the possibility of erosion into a branch of the superior pancreaticoduodenal artery.

Pathology.—At operation and even at autopsy it may be difficult to discover the source of the hemorrhage if bleeding has

stopped temporarily. Even in an old caloused ulcer where the dense fibrous tissue prevents the bleeding artery from retracting or collapsing the tiny orifice may be invisible unless it continues to bleed or is filled with a protruding clot. Still less easily visible is the open vessel in an acute ulcer because here it can both retract and collapse. Acute gastric catarrh is a frequent accompaniment of gastric hemorrhage and probably has some etiologic relationship to it. It is more frequent in the acute than in the chronic ulcer.

Symptoms.—Hematemesis and melena are the most frequent and obvious signs of gastric hemorrhage but they may be either preceded or followed by signs of severe internal hemorrhage: *e.*, dyspnea, thirst, pallor, vertigo, prostration or collapse, weak thread pulse and lowering of the blood pressure, hemoglobin content and erythrocyte count.

With these symptoms presented by a patient known to have a chronic or recurring ulcer it is a reasonably safe presumption that the hemorrhage comes from the ulcer. Where a history of pre-existent ulcer is lacking determination of the source of bleeding may require considerable time and effort just when both of these factors are precious. Filling of the stomach with a barium meal for fluoroscopic purposes may start up bleeding afresh or may cause an acute ulcer to perforate. Ulcer craters and tumors can usually be seen with the x-ray but acute ulcers can rarely be seen. The presence of an ulcer crater or a tumor in the stomach is presumptive although not positive proof that the lesion visualized is the source of the bleeding.

Diagnosis.—For surgical purposes it is necessary to know (1) that the bleeding is from the stomach, duodenum or intestine and is not from the esophagus, mouth, throat or lungs; (2) that the lesion from which the bleeding is coming is amenable to operation in contradistinction to pernicious matous hemorrhage, inoperable cancer or dilated veins accompanying cirrhosis of the liver; (3) whether the hemorrhage is continuing and at what rate and how much blood has been lost; and (4) where in the stomach the bleeding point lies so that it may be promptly found at operation and so

that no unnecessarily large incision in the stomach or prolonged hunting under anesthesia will be required.

When copious melena or hematemesis or both occur and the patient is known to have gastric ulcer it is reasonably safe for practical purposes to assume that an ulcer is the site of the hemorrhage provided always that careful examination of the patient reveals no other source of hemorrhage. The patient's general symptoms, blood pressure, pulse rate, blood examination and the amount of blood vomited and passed in the stools are the only criteria for determining how much the patient has bled and whether bleeding is continuing. Therefore only a rough clinical estimate can be made. Abdominal auscultation in a case of bleeding ulcer reveals the peristaltic sounds as loud, vigorous and continuous as after a full meal in marked contrast to intraperitoneal hemorrhage which always diminishes and often abolishes peristaltic murmurs. When the ulcer stops bleeding the sounds fade away to the faintness and infrequency of the fasting state until the diet is resumed.

The site of the ulcer may be known from previous x-ray examination. Otherwise a midline laparotomy incision will expose the stomach and the stomach wall can then be explored by hand, eye and diaphanoscopy (Rovsing). The interior of the stomach may be explored with the Rovsing gastroscope, an instrument which is similar to a single catheterizing cystoscope and the latter as well as the observation cystoscope has been used in place of the Rovsing instrument when that tool was not available. Rovsing's instrument is preferable however because of its wider field of vision which allows more rapid and certain inspection of the interior of the air-distended stomach. Moreover it has a larger light which is better for diaphanoscopy. The instrument is introduced through a small incision in the anterior wall after aspiration of the stomach contents with a purse string suture to prevent leakage of the content. The interior of the stomach is then examined by means of the instrument much as an air-filled urinary bladder is examined with a cystoscope.

Prognosis.—Even in severe and protracted hemorrhages the outlook for life is relatively good. As the blood pressure drops

with the Raising gastroscope or if no apparatus is available by direct inspection with the eye through a long anterior incision midway between the two curvatures. It should be borne in mind that a gastric ulcer usually lies along the lesser curvature and a bleeding duodenal ulcer on the posterior wall near the pylorus.

It is the test of a master surgeon to detect the correct time for intervention and to choose and execute the needed procedure after accurately locating the bleeding point. His choice has a wide range and includes simply backing out from parenchymatous hemorrhage, ligation or suture with or without packing of a bleeding point, underpinning sutures, ulcer inversion, ulcer excision with knife or cautery and with gastric or duodenal mobilization, pyloroplasty, gastrojejunostomy or gastric resection. (See the chapter on Gastric Surgery.) Resection carries in general the greatest operative risk but offers the most permanent cure especially of the large calloused ulcer.

When no ulcer or definite bleeding point is found on exploratory laparotomy, splenectomy has been performed with some apparent benefit in a few cases. However, it can not yet be considered a standard procedure.

GASTRIC WOUNDS

Etiology and Pathology.—Wounds of the stomach are usually classified as open or penetrating and closed or subcutaneous depending on whether or not the abdominal wall is penetrated or ruptured at the time of injury. *Penetrating wounds* are those caused by missiles usually gunshots, stabs

from knives and other sharp instruments and deep lacerations from machinery moving wheels falls against sharp objects and the like. *Subcutaneous wounds* are caused by blunt traumas such as blows, kicks, falls, automobile accidents, etc. A fully distended stomach, particularly if weakened by chronic alcoholism, scars or disease, may burst from a blunt injury insufficient to tear a collapsed stomach. In general, however, the stomach is tougher than the bowel, is somewhat protected by the ribs, particularly when it is empty, and is then less liable to blunt injury than is the bowel, liver or spleen.

The stomach when distended after meals or drinking bouts is particularly vulnerable to knife wounds, not only because of its increased size but also because it cannot yield or slip aside from the blade as readily as the small bowel, since it has no mesentery and since it lies directly against the rigid spinal column behind and the relatively unyielding liver and diaphragm above.

Subcutaneous rupture of the stomach from over distention by drink, gas (Seidlitz powders) or instrumentation (stomich tube gastroscope) is seen almost exclusively in stomachs friable from local disease. The same holds true for ruptures occurring after heavy lifting or excessive vomiting.

Laceration of the stomach by blunt violence (kicks and falls) is due to crushing against the spinal column. Even when the stomach is not perforated by the injury, peritonitis may ensue from suppuration of the mural hematoma or because the crushing is sufficient to make the wall permeable to pyogenic bacteria, even though not actually gangrenous. The liver or spleen is usually crushed at the same time, since they are both more vulnerable to crushing accidents than is the stomach. The pylorus and duodenum are less liable to injury.

Bursting lesions are usually in the form of longitudinal tears which tend to parallel the lesser curvature. The immediate flooding of the peritoneum with gastric contents and blood is so rapidly fatal that this rather rare lesion is seen more often by the pathologist than by the surgeon. It is extremely doubtful that the stomach is ever ruptured by voluntary contraction of the abdominal muscles as in straining or lifting unless it is friable from disease and distended.

Rarely do gunshot or revolver wounds of civilian life show the bursting effect on the stomach that has been noted by military surgeons. Even in war wounds it is infrequent as compared with the bursting effect of high velocity war missiles on the distended bladder and the brain. The small caliber and low velocity of the projectiles explain the relative absence of this phenomenon in civilian practice.

Symptomatology and Diagnosis.—The clinical picture of gastric injuries cannot be separated from that of abdominal wounds in general. The initial symptoms are those of hemorrhage and shock. Fat embolism is likely to occur when subcutaneous fat has been lacerated and crushed or bones have been broken. Hemorrhage is invariably present and the degree of shock usually varies roughly with the amount of blood lost. It is unfortunate that methods of measuring the amount of blood lost following injuries are so inaccurate that one seldom can be quite certain that the symptoms of so-called shock noted in an injured patient may not be due to loss of blood alone.

The diagnosis of perforating wound of the stomach is usually easy. An external wound is seen. The appearance of the wound and the patient's anamnesis indicate the nature of the weapon used. In *gunshot injuries* a wound of exit is looked for in addition to the wound of entrance or the flat of the hand is passed carefully over the skin on the opposite side of the body hunting for the spent bullet which often stops just beneath the skin. Pressure on the bullet if found elicits a point of tenderness. If not found by the hand it can be located with ease fluoroscopically, marks being made on the surface of the skin to indicate the location. A line connecting the bullet with the wound of entrance will indicate the path of the bullet through the body with admirable exactitude and a good anatomic atlas will indicate which organs have been penetrated. It is a common delusion that bullets bounce or curve in their path through the body as around ribs for instance. The fact is that when the course of the bullet deviates from a straight line its velocity is gone and it is no longer able to penetrate the tissues of the body to any material extent.

Allowance must be made for the fact that

the stomach and other mobile viscera lie somewhat lower in the abdomen in the standing than in the supine posture and that the stomach lies higher in fat persons than in thin. If the bullet's trajectory passes through or close to the normal position of the stomach a stomach tube is passed and the gastric contents are aspirated and examined for blood. Fluoroscopy may be used if there is enough air or fluid in the stomach to outline it and one can sight along the bullet's trajectory that is from the wound of entrance to the location of the bullet and see its relation to the stomach. If air has escaped from the stomach into the peritoneum it will be easily visible in the fluoroscope as it changes its location in the peritoneum with change of position of the patient. Pneumoperitoneum indicates perforation of a hollow gas containing viscus and if the line of the trajectory runs through the stomach it is logical to assume that the gas seen comes from the stomach. A perforating wound of the large bowel may also produce an almost immediate pneumoperitoneum but a wound of the small bowel usually does not lead to pneumoperitoneum until at least twenty-four hours has elapsed that is until there has been sufficient time for peritonitis to develop with gaseous distention of the small bowel.

In cases of *stab wound* inspection and probing often indicate its probable course and depth and also may fail to do so. The size and length of the weapon if known are some indication of the limits of penetration. There will usually be blood in the perforated stomach and an artificial pneumoperitoneum though seldom indicated can be produced as with gunshot wounds by inflating the well aspirated stomach via a Levine tube. A spontaneous pneumoperitoneum is not always present. In the case of a silent tense abdomen the presence of tenderness beyond the limits of the apparent wound requires surgical exploration even when probing fails to reveal penetration through the abdominal wall.

The stomach is rarely ruptured by *blunt violence*. Blunt injury sufficient to rupture the stomach is usually sufficient to rupture the liver, spleen or other abdominal viscera at the same time. Together with the specific signs and symptoms of gastric perforation

previously noted there are the general symptoms of perforation of an abdominal hollow viscus namely local pain and tenderness which gradually spread a silent rigid abdomen obstipation and nausea. From twelve to twenty four hours later as peritonitis sets in fever leukocytosis diffuse tenderness with rigidity and increasing meteorism develop. Thus the diagnosis of a perforated viscus becomes easily evident when operative or other therapy has become relatively hopeless.

Complications—The complications in general are those of injuries of the upper abdomen. The liver gallbladder spleen pancreas and large and small bowel may be injured simultaneously. A particularly difficult chapter of abdominal surgery is that of wounds involving the stomach diaphragm and organs of the chest especially on the left side. These are the so-called thoraco-abdominal wounds of the left upper quadrant. They may involve the liver spleen and splenic flexure of the colon as well as the stomach lung pleura and diaphragm.

Gunshots and stabs of the back below the level of the sixth rib on the left side are liable to penetrate the abdomen as well as the chest and must always be examined with that possibility in mind. Roentgen examination is of great value here in early diagnosis. Negative findings being almost as conclusive as positive findings.

The postoperative complications of gastric perforations are much like the postoperative complications of abdominal injuries in general chiefly hemorrhage and infection and their sequelae.

Prognosis—The prognosis depends on the character of the injury of the stomach and of the other abdominal viscera the amount of hemorrhage and infection the number of wounds the nature of the complications and the patient's general condition on admission to the hospital. Delay in seeking competent surgical aid is a serious and often fatal error.

Single small and not deeply penetrating wounds without complications which are promptly repaired by operation usually offer an excellent prognosis. Extensive multiple large and neglected wounds and their complications are associated with a high mortality rate.

Treatment—The management and surgical indications of gastric injuries can scarcely be considered apart from the injuries of the other abdominal viscera.

Penetrating injuries of the stomach must be repaired promptly by operation or the patient will die from hemorrhage or from peritonitis due to leakage. But a patient in shock with a feeble pulse cold hands and feet a sweating brow a blood pressure below 90 systolic and a low hemoglobin value and red cell count if operated on immediately will usually succumb on the table or shortly thereafter unless blood or plasma is available in generous quantity. The patient should first be made comfortable by morphine given intravenously (same dosage as for hypodermic administration). The stomach is aspirated and a Levine tube left in. No large incision is permitted. A snug scultetus binder is applied to the abdomen as soon as the morphine is effective. The binder reduces but does not always control venous hemorrhage and gastric leakage. It has still less control over arterial hemorrhage. Intravenous administration of electrolyte solutions is contraindicated (lest the clotting time be diminished and existing clots displaced by increasing blood pressure) until all hemorrhage has been controlled with certainty usually at operation. A blood plasma drip is started at once and is followed by citrated or heparinized blood as soon as the patient's blood can be typed and matched. The transfusion is continued while the patient is being wheeled to the operating room all during the operation during his return to bed and after he is in bed until the values for blood pressure red blood cells and blood protein have returned to approximately normal.

Until he is on the operating table the patient should be kept in the position in which the gastric wound is least likely to leak i. e. on the left side for a pyloric wound and on the right side for a wound of the cardia. If the systolic pressure rises quickly to 100 mm. the patient is probably a good operative risk. Patients known to have a normally high pressure must have the preoperative pressure raised accordingly.

These preparatory and stimulatory measures are practically the same as for other wounds of the abdomen and therefore will not be treated in further detail here.

Those surgeons who have whole blood and blood plasma easily and immediately available in large amounts from a blood bank need pay much less attention to the mitral blood pressure and to preliminary shock therapy than has been necessary in the past. The blood pressure can be built up even at the operating table and 'secondary shock' noted after the use of saline and dextrose solution practically disappears. Optimists go so far as to prophesy that immediate operation soon will be the rule in most cases of abdominal injury except when the patient is moribund.

The operation may be started under local anesthesia with morphine and scopolamine and as little ethylene ether or nitrous oxide and oxygen used subsequently as possible. Spinal anesthesia is time consuming and tends to lower an already too low blood pressure.

For a bullet wound the incision should be either midline paramedian on the side of the injury or transverse. Knife wounds are usually best explored by enlarging the wounds of entrance by a more or less muscle-splitting procedure. Generous incisions shorten these operations, make careful explorations easy, avoid excessive and painful pulling on the stomach or other viscera and permit a careful and effective abdominal toilet. When local anesthesia is used the peritoneum about the margins of the incision should be anesthetized by subperitoneal injection before wound retractors are applied, preferably self-retaining retractors. The anterior gastric wound is immediately closed by two or three layers of suture, the first of silk or linen and the second of catgut. Lambert sutures.

In cases of gunshot wounds it is even more important to find and close the wound on the posterior surface of the stomach than that on the anterior, because the former usually is larger and more likely to leak during subsequent dorsal posture. In the presence of an anterior wound it should always be assumed that there is a wound of exit elsewhere in the stomach (or rarely duodenum or esophagus). The failure to find it means a fatality if it is present. Single grazing wounds of the stomach are rare as compared with grazings of the small bowel. The same bullet in certain circumstances especially trans-

verse wounds may produce three or even four separate gastric perforations. A stab wound is usually single but may perforate through and through and may even be multiple.

At least two Lambert purse string or Z stitches should be used on each stomach perforation whereas a single stitch may often suffice for the small bowel. There is little likelihood of dangerous narrowing of the gastric lumen by two or even three layers of stitches while in the small bowel stenosis is much more of a liability.

The catching and ligating of bleeding points is usually the first step and the closure of the perforations the second. The electric aspirator is used to suck up the free fluid and blood in the peritoneal cavity and gauze packs placed beyond the field of operation tend to complete the drying process while the perforations are being closed. If much partly digested food is present in the peritoneum it is difficult to remove it completely either with forceps, aspirator or packs. The patient's general condition must determine how long a time may be spent in the effort to remove all food particles. It is doubtful if any kind of subsequent drainage of the abdomen is particularly effective either in avoiding or limiting subsequent peritonitis.

Thoracoabdominal wounds perforating the diaphragm are difficult to explore and repair particularly on the left side. Gunshot wounds are usually attacked best from an abdominal incision since the principal lesions are below the diaphragm and the diaphragmatic perforation can be closed from below. Stab wounds are best managed by enlarging them and exploring them to the bottom. For better exposure the adjacent ribs may be spread or one rib (rarely more) resected. With only a small cut in the skin there may be a long cut in the diaphragm with the stomach herniating through it and the contents leaking into the pleural cavity. The stomach may so plug the hole in the diaphragm that no appreciable leakage takes place into the abdomen even after twenty-four hours or the abdominal extravasation may be extensive.

The hole in the stomach is sutured, the bleeding omentum is ligated and stomach and omentum are returned to the abdomen. Stick sponges may be introduced into the

upper abdomen both in front of and behind the stomach to determine the presence of extravasated gastric contents or blood. If further abdominal exploration is indicated an upper abdominal laparotomy also is necessary.

The electric aspirator and stick sponges are used to clean and dry the pleural cavity before the stomach and omentum are reduced. The cut in the diaphragm is sutured and a catheter sewed into the chest wound for closed drainage. If the pleura is not soiled by gastric leakage the chest wall is closed tightly, the pneumothorax aspirated immediately by needle or trocar and the puncture opening sealed.

The combined thoracoabdominal operation consumes much time in the approach, the internal exploration and repair and the closure. It has a high mortality, around 50 per cent. The anterior osteoplastic flap operation on the lower left ribs gives good exposure of the structures in the left upper quadrant and of the diaphragm but is tedious and bloody, has a similar high mortality and occasionally a suppurative osteochondritis as a sequel. For small caliber wounds of the lung, diaphragm and upper cardiac portion of stomach where injury to the spleen and splenic flexure of the colon can be ruled out safely (fluoroscopic determination of the course of the bullet in relation to the gas-filled splenic flexure and the splenic shadow) the writer has used non-operative management in 12 cases with only 1 death and 2 subphrenic abscesses which healed after subsequent surgical drainage. In these cases the stomach is aspirated. Levine tube continuous drainage is started and the patient is turned to bed and kept on the right side so that all gastric contents will gravitate to the pars pylorica from which the Levine tube will aspirate it. All ingesta are withheld for at least a week.

The postoperative treatment of patients with gastric wounds differs but little in general from that of patients with abdominal wounds. Nothing is given by mouth for at least three or four days. During the first week the Levine tube is used almost continuously. The patient is supported by means of saline and dextrose solution administered subcutaneously or intravenously or both. Proctoclisis may be used subsequently when

the colon is known to be intact. Intravenous transfusion must not be given in amounts large enough to overload the heart muscle or to disturb the ionic balance of the blood plasma.

The subsequent treatment of symptoms and complications is about the same as in cases of other abdominal wounds. Fowler's position is not desirable since it tends to allow perigastric inflammation to spread downward. Perigastric and subdiaphragmatic abscesses which may develop subsequently require early diagnosis and evacuation. Intraperitoneal drains inserted at the primary operation are of doubtful value.

ROGER T. VAUGHAN

GASTRIC ULCER

Definition.—The term *gastric ulcer* implies a defect in the mucosa of the stomach with or without extension of the process to the deeper layers of the gastric wall. There are two distinct groups of gastric ulcers: (1) acute ulcers which are usually superficial and which tend to heal spontaneously and (2) chronic ulcers which are of long standing and which seldom heal without treatment. By far the more important group from the clinical standpoint is that of chronic ulcers.

Acute Gastric Ulcer.—Acute gastric ulcers may result from local trauma or may be part of a generalized process such as burn, uremia or arteriosclerosis (Fig. 530 B). The ulcers vary from a millimeter to several centimeters in diameter. They tend to be multiple and superficial. If they are not a part of a generalized condition which is in itself fatal, these ulcers usually heal rapidly and seldom require surgical intervention.

Chronic Gastric Ulcer.—The clinical problems connected with ulcer of the stomach are largely confined to the chronic type. In the remainder of the discussion the term gastric ulcer when used without qualification is understood to refer to chronic gastric ulcer. This lesion is closely related in most respects to duodenal ulcer. Although the two are probably caused by a common etiologic factor or factors and are similar in symptoms and in response to medical treatment, they differ widely in problems of dif-

ferential diagnosis and in surgical considerations. The greatest difference lies in the fact that ulcerations of the duodenum are very seldom malignant whereas the possibility of malignant disease must be kept constantly in mind in dealing with ulcerations of the stomach.

Incidence.—The incidence of gastric ulcer is greater in the races of Europe and the United States than it is among primitive peoples. It is probable that about 10 per cent of the population of Germany, France, Great Britain and the United States have at some time a chronic ulceration of the upper portion of the gastrointestinal tract. Although postmortem studies have shown an almost equal frequency of gastric and of duodenal ulcer, the latter appears to be encoun-

amount of free hydrochloric acid in the gastric contents has long been considered a probable factor in the production of gastric ulcer. Its presence seems to be essential not only to the formation of the lesion but especially to its chronicity. Moreover control of the acidity by various types of medication leads to relief of symptoms and subsequent healing of the ulcer. However ulcers usually do not occur in those areas of the stomach which are richest in acid-secreting cells. Although the acid factor seems definitely related to the persistence of a gastric ulcer, it is not sufficient to account for the onset of the lesion.

2 Trauma.—Trauma of itself does not lead to chronic gastric ulcer. Surgical defects in the stomach heal readily and be-

Fig 530—1 Diagrammatic cross section of the stomach showing the common location of a gastric ulcer on the lesser curvature. B Schematic sections of the stomach wall showing acute, chronic and healed gastric ulcers.

tered much more often by the clinician. The estimates range from 1:4 to 1:14.⁵ Gastric ulcer occurs four times as often in men as in women. It may develop at any age but reaches its peak between the ages of thirty and fifty.

Etiology.—The many theories which have been suggested as to the underlying cause of gastric ulcer indicate by their very number that the exact etiologic factor is unknown. It is possible that several factors may operate to produce the same end result and that a chronic indurated ulcer may result from different processes in different individuals. Of the possible factors which have been suggested, the ones presented here seem most worthy of attention at the present time.

1 Acid Factor.—The presence of a large

have more like acute gastric ulcers. On the other hand, trauma may operate in conjunction with other factors to produce the chronic type of lesion. The fact that the majority of gastric ulcers occur along the lesser curvature and in the antrum of the stomach suggests that the mechanical action of the stomach, which forces the gastric contents against the stomach wall at this point, may play a role in ulcer formation.

In experimental studies, artificially produced gastric ulcers on the lesser curvature heal more slowly than those on the greater curvature. Similarly, the healing of defects produced by excision of portions of gastric mucosa is greatly retarded if a rough diet is given. Thus again suggests that trauma is an important secondary factor in the forma-

tion of gastric ulcer but that in itself it is not sufficient to initiate these lesions. The experimental observations have a direct clinical correlation because they are in accord with the beneficial results obtained with bland diet in the medical treatment of gastric ulcer as well as in the postoperative care of patients who have had an operation for gastric ulcer.

3 Vascular Factor—According to some authorities lesions of the submucosal vessels are of significance in the production of chronic ulcerations of the gastric mucosa. If these lesions have a definite bearing on the production of chronic ulcers it should be possible to find them in surgical specimens or at autopsy in a large percentage of cases. However the thrombi and lesions of blood vessel walls occasionally seen in the neighborhood of gastric ulcers are in general to be regarded as the result of secondary changes in the area of the lesion. It is possible however that a state of long continued vascular spasm may have some relation to the production of gastric ulcer.

4 Neurogenic Factor—There is a strong clinical impression that severe nervous and emotional strain bears a direct relation to the onset of gastric ulcer in many patients. Furthermore the mental status of a patient with known gastric ulcer has an important bearing on his improvement under treatment. Recurrences are very frequently correlated with the repetition of severe emotional strain. These clinical observations have led to extensive consideration of the etiologic relationships between neurogenic factors and the development and persistence of gastric ulcers. This relationship was clearly stated by Rokitsansky and was revived in more recent years by Cushing.³ Cushing pointed out the frequency of the development of acute peptic ulcers in lesions of the interbrain and produced strong arguments in favor of the relationship of neurogenic factors and gastric ulcer. None of these studies however clearly elucidated the specific mechanism by which the neurogenic influences lead to the production of chronic gastric ulcer. It is possible that neurogenic factors produce long repeated or continuous spasm of the blood vessels with resulting necrosis of the mucosa. It is possible also to assume that the blood vessels

are constricted by spasm of the surrounding musculature. In either case there might be no demonstrable change in the vessels as seen at postmortem examination or in the resected surgical material. For this reason the neurogenic factor offers a possible but as yet incompletely demonstrated basis for the etiology of gastric and duodenal ulcer.

5 Miscellaneous Factors—Numerous other factors have been suggested as responsible for the formation of gastric ulcer but thus far clearest experimental and clinical evidence has not been forthcoming. Infection by itself is almost certainly not a cause of ulcer but the onset or recurrence of the symptoms of gastric ulcer may coincide with an acute infection. The unsatisfactory physical condition of a patient which accompanies such infection might appear to be the element involved rather than the infection itself.

Endocrine factors may influence the formation of gastric ulcer. Ivy⁷ has put forward evidence for the possible relation of several hormones especially enterogastrone to the development of gastric ulcer. The role of these various gastrointestinal hormones in the production of chronic gastric ulcer has not been completely elucidated but the investigation of these hormones offers an important field for study.

Pathology—Chronic gastric ulcers are located in the majority of instances along the lesser curvature about the incisura angularis and in the prepyloric region (Fig 530 A). Some of them are round while others are oval with the long axis transverse to the long axis of the stomach.

A typical gastric ulcer shows a defect in the mucosa which may vary in diameter from a few millimeters to several centimeters. The glands of this layer are hyperplastic at the edges of the defect. The margins of the ulcer tend to be undermined and to extend beyond the region at which the mucosa is interrupted (Fig 530 B). The submucosa is also eroded and in most instances the ulceration extends for a distance into the muscularis. The edges of the ulceration are made up of scar tissue. Part of it is composed of old collagenous connective tissue indicating that the process has been going on over a considerable period of time. Other portions show actively proliferating

fibroblasts and blood vessels indicating that the process of repair has continued up until the time of examination. The process therefore represents the repair of a long continued injury.

If there are large vessels close by they sometimes show moderate thickening of their walls. Rarely thrombi are observed but there are no constant vascular lesions about the ulcer. The presence of large vessels in the region of these ulcerations is important because they may become eroded with consequent hemorrhage.

Perforations result from continued penetration through the wall and the serosa. However penetration may be so deep even without perforation that the roentgenogram suggests a diverticulum. The depth of the gastric ulcer as seen in roentgenograms is considerably increased by the amount of edema about the lesion. The rapid diminution in size of the filling defect when treatment has been instituted is largely a result of the disappearance of this edema.

A considerable amount of scar tissue is produced in the healing of gastric ulcers especially if they are large. With the contraction of the scar tissue deformity of the stomach results. When this occurs near the center of the stomach an hourglass constriction is formed (Fig. 531) if it takes place in the prepyloric region narrowing of the pylorus is the result. When the degree of constriction is great enough to interfere with the passage of food there is hypertrophy of the musculature proximal to the region of obstruction.

The inflammatory reaction which surrounds the ulcer leads to considerable induration especially when fat tissue has become necrotic. This reaction is difficult to distinguish from a malignant lesion especially when the specimen is studied only in the gross.

In making a microscopic examination of a gastric ulcer it is important to examine many portions of the lesion before it is stated definitely that malignant disease is absent. Now that earlier examples of gastric ulcer are discovered as a result of the improvement in roentgenographic diagnosis the pathologist sees a greater number of small lesions which contain evidence of early malignant growth. Mallory⁸ described a

series in which the lesion was so early that even microscopically it was difficult to decide whether the condition was definitely carcinomatous or not. By securing such lesions for study progress can be made in understanding the pathogenesis of these lesions and more successful treatment can be instituted.

Symptoms.—The symptoms of gastric ulcer are so variable that a classic syndrome can hardly be defined. Indigestion and epigastric pain are the most frequent complaints. Indigestion is interpreted differently by each patient and may be described as a feeling of hunger, fullness or burning or a gnawing sensation associated with heart burn and sour eructations. The distress is

Fig. 531.—Central constriction associated with a chronic gastric ulcer of long standing producing hourglass constriction of a B. stomach.

usually relieved temporarily by the taking of food or alkalis but recurs within one to two hours after meals. Frequently the symptoms last for years with intermittent periods of relative freedom from distress. Periodicity is far less common with gastric than with duodenal ulcer. The periodicity is explained by the fact that ulcer is a chronic disease which tends to recur from time to time owing to such predisposing factors as indiscretions in diet, worry, fatigue and infection.

The pain varies from a dull gnawing sensation in the epigastrium to a severe stabbing pain depending upon the location of the ulcer and the degree of penetration. A posterior penetrating ulcer commonly produces pain which is referred to the back. If

perigastritis is present about the ulcer the pain may be aggravated by eating.

Bizarre symptoms may be present owing to interference with the motor function of the stomach. Vomiting and difficulty in swallowing may result from cardiospasm when the ulcer is high in the stomach. Vomiting with signs of pyloric obstruction may be present owing to pylorospasm or deformity caused by an ulcer in the prepyloric region. Symptoms of obstruction may appear as a result of the development of an hourglass constriction of the stomach. These secondary effects of the ulcer may bring about a confusing clinical picture.

Physical Signs—The patient with gastric ulcer may or may not show positive physical signs depending upon the location of the ulcer and the possibility of an associated complication. Rigidity and tenderness of varying degrees may be present in the epigastrium when the ulcer is active and penetrating. These findings are more marked when the patient is having pain from the ulcer. When there is marked interference with the normal motor function of the stomach the patient may show considerable weight loss and dehydration from inability to take or retain food.

While the physical examination offers little evidence to substantiate the diagnosis of gastric ulcer it must not be slighted for it may disclose definite information as to the degree of penetration or as to possible complications or it may disclose other sources of disease which produce symptoms mimicking those of gastric ulcer.

Special Examination—1 *Gastric Analysis*—There is no specific finding by gastric analysis which is diagnostic of gastric ulcer. However from gastric analysis information may be obtained which is of value in the treatment of the ulcer and is possibly an aid in the differential diagnosis from carcinoma. The concentration of hydrochloric acid in gastric secretions averages about 30 per cent above that of the normal person.⁵ A progress in lowering of the acidity at intervals of three weeks suggests that the ulceration is malignant. Absence of free hydrochloric acid usually indicates the presence of carcinoma rather than of benign ulceration.

Occult blood if present in several gastric analyses implies an active ulcer or car-

cinoma. However it often happens that an occasional positive reaction for blood is obtained as a result of trauma during aspiration.

2 *Stool Examination*—Examination of a stool specimen for occult blood should be made routinely. The persistent finding of occult blood when the patient is under treatment should raise the question of malignant disease.

3 *Roentgenologic Examination*—Roentgenologic examination is undoubtedly the most valuable diagnostic aid available today to the physician because it not only confirms the presence of an ulcer but it discloses the exact size and location of the lesion. In addition it gives a relative idea of the activity of the ulcer and the response to subsequent medical treatment. Most important of all it helps to differentiate between a benign lesion of the stomach and carcinoma.

Gastric ulcers along the lesser curvature characteristically show a diverticulum like projection of barium which is known as a niche (Fig 53²). This outlined pocket projects beyond the normal limit of the gastric wall as a result of the penetration of the ulcer and the edema of the adjacent mucosa and submucosa. The rugae adjacent to the ulcer are frequently accentuated and may converge toward the crater. Peristalsis is present up to and below the ulceration unless there is penetration of the ulcer with surrounding induration and fixation. The ulcer crater is usually tender to palpation. Opposite such an ulceration may be a spastic contracture (incisura) of the greater curvature. Occasionally in a chronic ulcer of long duration the greater curvature is drawn toward the ulcer by scarring thereby dividing the stomach into two parts and producing the so called hourglass deformity, or B stomach (Fig 5²¹).

In contrast to the diverticulum like appearance of benign ulcers malignant ulcers are usually shallow irregular and cancer like in appearance without tenderness to palpation. They are frequently larger than benign ulcers as a result of the central necrosis. If there are slight irregularities about the margin from tumor masses the diagnosis of carcinoma is established. In carcinoma the peristaltic waves are obliterated and fre-

quently the mucosal pattern about the ulceration is distorted owing to infiltration of the tumor

The roentgenologic examination also shows the amount of retention following the six hour meal of barium. Since gastric ulcers produce changes in the gastric physiology a moderate amount of barium retention commonly occurs as a result of interference with gastric motility. Repeated fluoroscopic studies give information as to the effectiveness of medical treatment in controlling the retention.

Investigation establishes whether the lesion is benign or malignant when other methods of investigation are not sufficient to make this differentiation and at a time when successful treatment may be instituted.

Differential Diagnosis—Since the symptoms of gastric ulcer are so variable it is often difficult to differentiate ulcer from many other lesions both within and without the gastrointestinal tract.

Chronic cholecystitis may produce symptoms simulating those of gastric ulcer but the location and radiation of the pain in gall

Fig. 550.—Diagram showing the configuration of a gastric ulcer. The deep base and relatively narrow neck of the ulcer crater when filled with barium give the appearance of a diverticulum in the roentgenogram. This diagram also shows the reflex symptoms at the cardia or the pylorus produced by a gastric ulcer.

The primary consideration of the roentgenologist then is two fold. He must confirm the clinician's impression of gastric ulcer and determine as soon as he can whether the ulceration has any of the characteristics of carcinoma. The roentgenologic examination should be repeated after three weeks of medical treatment.

4 Gastroscopy—The gastroscope allows actual visualization of the stomach wall. Its use as a diagnostic procedure in cases in which roentgenologic examination leaves some doubt has become increasingly important. By means of this procedure the lesion can be visualized and material secured for biopsy. In many instances this method of

bladder disease together with the aggravation of symptoms by the ingestion of fried and fatty foods should suggest gallbladder disease. If not the physical and roentgenologic examination of the stomach and gallbladder should clarify the diagnosis.

Inflammatory lesions involving the terminal ileum, appendix or right colon are known to produce symptoms referable to the epigastrium similar to those of gastric ulcer. However, absence of relief by food and antacids as well as the presence of pain and tenderness in the right lower quadrant should focus attention on this area. Likewise symptoms of carcinoma of the right colon may be similar to those of gastric

ulcer The existence of such lesions in addition to gastric ulcer should not be overlooked

Gastritis without ulceration does not give a typical ulcer syndrome and the symptoms may be exaggerated rather than relieved by the taking of food Here again roentgenologic and gastroscopic examination give in valuable aid in making the diagnosis A gastric crisis due to syphilis may simulate that due to a gastric ulcer but this is a rare occurrence It should be borne in mind that syphilitic patients may also have gastric ulcer Free hydrochloric acid is frequently absent in the presence of gastric syphilis

Reflex symptoms from other systems such as the genitourinary and nervous systems may be confused with those of ulcer While the periodicity of ulcer symptoms combined with the temporary alleviation of the complaint following the taking of antacids and food may suggest the diagnosis of gastric ulcer the final diagnosis invariably depends upon the roentgenologic examination with barium

The symptoms of gastric and duodenal ulcer are so similar that a differential diagnosis is frequently impossible from the history and physical findings A shorter period of relief after meals usually follows in the presence of gastric ulcer but this is not an infallible guide The point of maximum tenderness in the upper abdomen may give a clue to the location of the ulcer Patients with gastric ulcer are on the average ten years older than those with duodenal ulcer Because of the danger of carcinoma associated with gastric ulcerations the diagnosis of gastric ulcer should not be delayed while diet and medication are tried but should be made immediately by roentgenograms

Once it has been determined that there is ulceration of the gastric mucosa the clinician must decide if possible whether the lesion is benign or malignant Since approximately a third of the patients with carcinoma of the stomach give a history consistent with gastric ulcer in all respects including temporary improvement from diet and medication the only safe attitude to assume is that any gastric ulcer is potentially malignant until proved otherwise

It is sometimes impossible to determine by the various laboratory examinations in-

cluding roentgenographic study whether a small gastric ulcer is benign or malignant until its response to medical treatment has been determined The problem is all the more difficult because over one third of the patients with carcinoma have a normal gastric acidity and some show a temporary decrease in the size of the ulceration following medical treatment The complete disappearance of a small carcinomatous lesion in the roentgenogram is rare but may occur

Certain criteria have been established to aid in differentiation depending upon the location and size of the ulcer as well as the response to medical treatment Gastric ulcerations in the prepyloric region have a three out of four chance of being malignant⁸ This is especially true of those located in the 2.5 cm of stomach adjacent to the pylorus⁹ Ulcerations along the greater curvature are practically always due to carcinoma Similarly large ulcerations that are those over 3 cm in diameter are considered potentially malignant If by fluoroscopic examination the gastric ulcer is found to have any of the characteristics suggestive of neoplasm a second examination should be made after three weeks of medical treatment Gastroscopic study may be helpful in making an early diagnosis of carcinoma in these borderline lesions In such cases strict medical treatment including bed rest is prescribed for a period of three weeks

Scott and Mider¹⁰ have advocated resection of a gastric ulcer which does not respond to strict medical management as demonstrated by a diminution of symptoms and occult blood in the stool the second week and the disappearance of the filling defect noted fluoroscopically by the end of the third week A very large ulcer should decrease in size by at least one third after three weeks of medical treatment The menace of cancer requires constant vigilance since there is more or less general agreement that 5 to 10 per cent of all gastric ulcers become malignant

Complications—The majority of gastric ulcers respond satisfactorily to medical treatment however the complications of gastric ulcer often require surgical intervention The common complications of gastric ulcer are hemorrhage perforation and obstruction

1 Hemorrhage—Bleeding occurs in about

10 to 20 per cent of all cases of gastric ulcer at some time during the course of the disease.¹¹ An ulceration along the lesser curvature may penetrate and erode one of the larger vessels causing serious hemorrhage (Fig 533 B). Similarly an ulceration on the posterior wall of the stomach which has penetrated into the pancreas may give troublesome bleeding (Fig 533 C). If one of the large vessels such as the splenic artery is perforated massive fatal hemorrhage may occur.

The symptoms produced by bleeding from a gastric ulcer depend upon the size of the vessel eroded and the amount of blood lost. The patient may notice no more than weakness and tarry stools but if a large vessel has eroded hematemesis and symptoms of shock may appear.

the clot formation in the bleeding vessel. With the advent of the blood bank quantities of blood may be stored for use as a constant intravenous drip. Sufficient blood should be available to administer at any time. The administration of blood plasma also has an important place in the treatment of these patients especially when shock is present.

After the patient has been brought into good condition medical therapy is instituted. Some physicians prefer to withhold food by mouth for a few days and then to institute a regular regimen of alkaline therapy and frequent feedings after the method of Sippy. Others following the suggestion of Meulengracht start alkaline therapy and frequent feedings immediately. Since the majority of these patients respond satisfac-

FIG. 533.—Schematic representation of complications of gastric ulcer requiring surgical treatment.

TREATMENT—The immediate problem in the treatment of massive hemorrhage from a gastric ulcer is to combat the acute blood loss. The pulse rate and blood pressure should be taken at frequent intervals and a complete analysis of the blood including a complete blood count and hematocrit and total plasma protein determinations should be made in order that all possible information as to the amount of blood lost may be obtained. This information serves as a guide to the time for and the amount of replacement therapy necessary. Blood transfusions should be given to maintain the systolic blood pressure at a level of 70 mm. or above but no effort should be made to elevate it to the prehemorrhage level because of the danger of disturbing

torily to medical treatment it is a difficult problem to select for early operation those individuals who might otherwise bleed to death.

No unanimity of opinion exists regarding the time and type of surgical procedure to be performed. Each instance of massive hemorrhage from gastric ulcer is an individual problem. So many patients with massive hemorrhage recover under medical treatment that the surgeon hesitates to operate upon any one suffering from acute blood loss. Moreover the surgeon may be uncertain of the actual source of the hemorrhage especially in cases in which previous roentgenologic studies have not been made. He knows from experience that the actual

bleeding point may not be found at operation. The bleeding may be from esophageal varices or gastritis instead of from an actively bleeding ulcer thereby making control of the hemorrhage impossible. However ligation of the bleeding vessel is imperative if the patient continues to show evidence of active bleeding despite repeated transfusions.

If the patient is under 50 years of age surgical treatment may be delayed because the mortality on medical treatment is less than 10 per cent. If the patient is over 50 years of age the mortality is approximately 30 per cent.¹ Because of this increased mortality in the older age group early surgical intervention has been recommended in this group—within forty-eight hours of the onset of massive bleeding. Regardless of the age of

Repeated massive hemorrhage is an indication for surgical intervention regardless of the age of the patient.

2 Acute Perforation—Acute or free perforation occurs most often on the anterior wall of the stomach (Fig. 534 A). Over 60 per cent of perforated gastric ulcers occur in patients over 40 years of age. In the majority of instances a history suggestive of ulcer may be attained but in a considerable number of instances perforation occurs in patients who have had no previous symptoms characteristic of gastric ulcer.

As a result of the escape of gastric contents into the peritoneal cavity there is a sudden severe agonizing pain in the epigastrium which soon spreads throughout the entire abdomen. In the first hour or two after per-

Fig. 534.—A Biopsy of a perforated gastric ulcer to determine the presence or absence of malignancy. B Technique of closure of a perforated gastric ulcer.

the patient the surgeon usually prefers to delay operation for a trial of transfusion and medical treatment unless there is evidence of persistent acute loss of blood despite repeated transfusions.

In the presence of active bleeding the type of surgical procedure depends upon the condition of the patient and the technical difficulties encountered. Only the active bleeding should be stopped by the direct insertion of silk sutures in the ulcer bed. In the presence of active hemorrhage the aim of the surgeon is to save life by controlling the bleeding vessel. Further surgical procedures at this time add considerably to the operative mortality. If these procedures are necessary they should be carried out at a subsequent operation.

After perforation there may be signs of shock with a sudden fall in temperature. The respirations become short and grunting and there is characteristic board-like rigidity of the abdomen, which is of great significance in the initial shock. Symptoms of spreading or generalized peritonitis rapidly become well established. The finding of free gas in the peritoneal cavity (pneumoperitoneum) either by roentgenograms or occasionally by physical examination definitely establishes the diagnosis. In order to determine the presence or absence of free gas in the peritoneal cavity the roentgenogram is made with the patient in an upright position so that gas if present will appear as crescents beneath the diaphragm. If the patient is too ill to be placed upright he may lie on his left side

If free gas is present it will then appear as a bubble above the liver. Shoulder pain may be present as a result of irritation of the dome of the diaphragm referring the pain by way of the phrenic nerve. Likewise the liver dullness may be obliterated to percu-ssion. It is usually impossible (and of academic interest) to determine from the history and physical examination whether the perforation has occurred in the duodenum or in the stomach. In either case it is imperative that the perforation be closed as soon as the patient has recovered from shock.

The differential diagnosis is at times difficult depending on the duration of the perforation and the reaction of the patient. The clinical picture may suggest acute pancreatitis, acute cholecystitis, biliary or renal colic, appendicitis with generalized peritonitis and at times coronary thrombosis. A careful history combined with the characteristic board-like rigidity of the abdomen and the sudden onset of the pain are the most important factors in making the correct diagnosis.

The patient is placed on constant gastric suction to prevent further escape of the gastric contents into the peritoneal cavity and to avoid the possibility of aspiration of the gastric contents by vomiting during and after anesthesia. The administration of blood plasma intravenously is of great importance and may be supplemented by physiologic saline solution if dehydration is present.

No further surgical procedure beyond the closure of the perforation should be attempted at this time because it would increase the mortality rate. However in view of the ever present danger of carcinoma in gastric ulcerations a very small section of the gastric wall adjacent to the perforation may be removed for biopsy (Fig 534 A). Especially should this be done if the perforation is in the prepyloric area or about the greater curvature or if the appearance of the lesion is at all suggestive of neoplasm. Even if the surgeon is certain that the perforation has occurred in a carcinoma he should merely close the perforation and leave resection for a subsequent operation after the patient has recovered. As much as possible of the infected material from the abdomen should be removed by suction.

Cultures of the peritoneal fluid are always taken. One of the sulfonamide group in powder form may be introduced directly into the peritoneal cavity to combat the peritonitis. Penicillin may also be used. Drains are usually omitted except under certain circumstances when organisms are demonstrated in direct smears of the peritoneal fluid.

Constant gastric suction is maintained for several days after operation. Nothing is given by mouth and fluids are administered intravenously. Chemotherapy may be instituted if cultures of the peritoneal fluid are positive.

The immediate postoperative complications are most frequently pulmonary such as atelectasis or bronchopneumonia. Of equal importance is the result of infection such as generalized peritonitis, subphrenic abscess or wound infection. Perforated gastric ulcers as a rule have a higher mortality rate than perforated duodenal ulcers probably owing to the fact that the former usually occur in the older age group. The mortality increases progressively as the interval lengthens between the time of perforation and the time of closure. The prognosis is better if the perforation occurs when the stomach is empty and if the culture of the peritoneal fluid at the time of operation is negative.

Although some surgeons feel that perforation results in the cure of that particular ulcer, long range figures do not bear this out. The great majority of patients with perforated ulcers who have been followed for a long period require an additional surgical procedure because of recurrence of ulcer symptoms.

3 Late Perforations—If a patient is first seen forty-eight hours or longer after perforation of the gastric ulcer and if he is still in good physical condition it is usually an indication that the perforation has been walled off. Under these circumstances it is safer to avoid operation and to continue constant gastric suction and intravenous administration of fluids than it is to carry out immediate operation. Certain patients who are first seen a day or two after perforation and who are in very poor condition as a result of generalized peritonitis may survive if conservative therapy is instituted whereas they would succumb to immediate surgical

intervention. In any case large quantities of whole blood or of blood plasma should be administered.

4 Subacute Perforation—Subacute perforation is one through which the gastric contents leak slowly or one which is sealed off by omentum or adjacent structures before much leakage can occur. These perforations present great difficulty in differential diagnosis. The gastric contents may be directed down the right lumbar gutter producing symptoms simulating those of cholecystitis, renal disease or appendicitis. Localized abscesses about the stomach or a subphrenic abscess may occur requiring subsequent incision and drainage.

5 Chronic Perforation—A chronic perforation occurs most frequently on the posterior wall of the stomach and may become of surgical importance because of pain and failure of response to medical treatment (Fig. 533 C). The perforation is walled off by an adjacent structure such as the pancreas which prevents leakage of the gastric contents. Such chronic perforations are often resistant to medical treatment and have a tendency to bleed. The diagnosis and localization of this type of lesion depend largely upon physical and roentgenologic examination. Subtotal resection of the stomach may be necessary.

6 Obstruction—Gastric ulcers commonly produce evidence of gastric retention as a result of interference with gastric motility due to spasm, cicatricial contraction, edema or hypertrophy of the pylorus.

As a result of the obstruction the patient has distress and a feeling of fullness in the epigastrium especially marked toward the end of the day. This distress is relieved by vomiting. When the obstruction is severe vomiting may be so frequent that the patient becomes emaciated and dehydrated with evidence of tetany due to alkalosis.

The diagnosis of complete obstruction is usually obvious. However lesser degrees of obstruction can be verified and evaluated by roentgenograms following a six hour barium meal. The diagnosis may likewise be confirmed by aspiration with the stomach tube and measurement of the amount of gastric contents withdrawn.

Treatment—Medical treatment should be given a trial even though the roentgeno-

gram may show 100 per cent retention of barium with a six hour meal. Often the retention due to spasm and edema may be overcome and only then may the amount actually due to cicatricial contraction be determined. Occasionally the retention is entirely controlled by medical treatment and surgical intervention is unnecessary.

Medical treatment consists of the administration of antispasmodics such as tincture of belladonna, antacid therapy and daily aspiration of the stomach. From the amount of gastric contents aspirated the physician can estimate whether the obstruction is increasing or decreasing. An effort is made to improve the general condition of the emaciated patient by the administration of a high vitamin high caloric diet consistent with his ability to retain nourishment. The alkaline therapy in complete obstruction more recently has included the administration of non absorbable neutralizing agents such as aluminum hydroxide or magnesium trisilicate to prevent disturbance in the acid base balance. If under a strict medical regimen the retention persists at 40 per cent or more following a six hour barium meal operation is indicated.

Patients with obstruction are often suffering from malnutrition, dehydration or alkalosis. In addition the stomach is so distended that it must be decompressed by constant gastric suction before any type of surgical procedure can be carried out. Otherwise the anastomosis may be distorted and disaster may follow operation. If there is evidence of dehydration or alkalosis the operation is delayed until the electrolytic balance is corrected. When obstruction is complete and the general condition of the patient is quite poor feeding by means of jejunostomy may be advisable to be followed later by a surgical attack on the gastric lesion.

While gastroenterostomy is an ideal procedure in the presence of pyloric obstruction its use in the presence of gastric ulcer must be guarded because of the danger that the lesion may be malignant.

If the symptoms of obstruction resulting from hourglass constriction cannot be overcome by medical treatment gastric resection may be necessary to correct this deformity (Fig. 532).

Principles of Treatment —1 Medical— Most gastric ulcers are benign and will heal without surgical intervention if adequate medical treatment is carried out. This consists of a non irritating diet and medication supplemented by an attempt to improve the general condition of the patient. Any focus of infection should be eradicated. It is important that an effort be made to improve the psychologic attitude of the patient so as to insure freedom from worry. The medication may vary but always consists of the administration of some form of antacid at frequent intervals. Belladonna or atropine is given to overcome spasm which interferes with gastric motility and in some instances it is supplemented by a sedative. Because of the danger of carcinoma the patient with gastric ulcer must be kept under rigid supervision preferably in bed in the hospital until the ulcer has healed.

2 Surgical. A Failure of Medical Treatment—In general unless the surgeon is familiar with the quality and duration of the medical treatment he should recommend operation only for the complications of ulcer. However a small group of patients especially those with an ulcer of the posterior penetrating type continue to have pain and distress despite adequate medical treatment. For these patients resection is advisable. Occasionally because of financial status a patient may be unable to continue medical treatment for a sufficient length of time to effect a cure. In such instances surgical treatment may be considered. The surgeon should not recommend it as a means of escape to those who are unwilling to adhere to the restrictions of diet imposed by medical treatment or to those who are intemperate in their habits.

B Suspicion of Cancer—The primary consideration in the treatment of gastric ulcer is to rule out the possibility of carcinoma and to make certain that early eradication is undertaken if the location or progress of the lesion is at all questionable. The clinician should consider the possibility of carcinoma if the ulcer is located in the prepyloric mesh or on the greater curvature of the stomach if it is larger than 3 cm. regardless of location and if it fails to show sufficient improvement after three weeks of adequate medical treatment. Even though

the patient is under forty years of age has high acid values in the gastric secretions and apparently improves clinically and roentgenographically he may harbor a malignant lesion. Therefore every patient with gastric ulcer demands constant supervision and the closest cooperation among physician roentgenologist and surgeon.

C Choice of Operation—There is no standardized surgical procedure for the treatment of gastric ulcer. The complication involved the general condition of the patient the possibility of carcinoma and the technical difficulties to be overcome govern the choice of procedure.

The incidence of jejunal ulceration is not nearly so great after surgical procedures for gastric ulcer as it is for duodenal ulcer. Therefore it is not so necessary to reduce markedly the volume of gastric juice secreted in order to prevent recurrent ulceration. A wedge shaped excision of the ulcer with the addition of gastroenterostomy often effects a cure. However at the time the ulcer is removed immediate examination of a frozen section should be made to rule out the presence of carcinoma.

Occasionally a posterior penetrating ulcer may be technically impossible to remove. If so the ulcer bed may be craterized the edges of the ulcer excised and the stomach wall reapproximated.

If there is any question of carcinoma a radical resection which includes the lymph gland drainage area should be carried out if the general condition of the patient permits. Usually the duodenum is closed and the jejunum is anastomosed to the remaining portion of the stomach by any one of a variety of methods. Because of the existent relationship between gastric ulcer and carcinoma there is an increasing tendency to carry out radical resection for gastric ulcer. The mortality for resection is steadily decreasing and is now in the neighborhood of 5 per cent.

After operation the patient must be cautioned that it is just as important for him to avoid irritating foods alcohol and excess smoking as it was before operation.

Prognosis—Gastric ulcer has a tendency to recur over a period of years. In general the prognosis of gastric ulcer must be guarded because of the possibility of car

ENOMA For that reason every patient with gastric ulcer should be followed closely for an indefinite period by his clinician and should have his progress checked fluoroscopically and roentgenographically at regular intervals. Even though the immediate response to medical treatment may be good and further treatment may appear unnecessary, an occasional patient returns with inoperable carcinoma of the stomach. For that reason a patient with an ulceration especially in the so-called danger areas if not subjected to surgical treatment should be given a guarded prognosis and should be supervised closely by a physician, roentgenologist and surgeon. Postoperative results for gastric ulcer over a long period are good and are much better than those for duodenal ulcer.

TUMORS OF THE STOMACH

The frequency of occurrence of various tumors of the stomach is given in Table 6. Carcinoma involves the stomach more frequently than does any other organic lesion.

It usually occurs on the lesser curvature and on the posterior wall but may be situated in any portion of the stomach. Involvement of the adjacent or surrounding lymph nodes is usual and the extent to which this has taken place determines more or less whether or not removal is possible. MacCarty has considered that carcinoma is derived from the glandular cells of the mucosa and that it may arise in three structural situations: (1) in the borders of chronic gastric ulcers (2) in adenomatous tumors such as poly-

roid (Fig. 535) or cauliflower growths as parts of the pedunculated polyps and (3) possibly in regions of chronic gastritis without the presence of an ulcer or polyp. The essential features of the tissue pathology of the other tumors of the stomach according to MacCarty are as follows:

Sarcomas or malignant neoplasms of mesoblastic origin in the stomach are not uncommon. The diffuse lymphoblastic sarcoma is the most frequent and is composed of malignant lymphoblasts. The histologic

and cytologic picture being indistinguishable from those seen in Hodgkin's disease, lymphatic leukemia and lymphosarcoma. It occurs usually as a localized lesion in the stomach although it has been seen as a diffuse condition involving all the gastric coats. Lymphoblastic sarcoma also produces a diffuse thickening of the gastric wall which may be irregularly and even nodularly enlarged making the gross differential diagnosis between carcinoma and sarcoma often difficult and usually impossible without microscopic study.

Single and multiple *polyps* in the stomach are relatively rare. They occur in all the portions of the organ and may or may

not infrequently be seen in association with pyloric obstruction. It is the function of the surgical pathologist to determine which myomas, fibromyomas and fibromas also are sarcomatous.

Angiomas, lipomas and fibromas are relatively rare but they may originate in any part of the gastric wall. A tumor of one of these types may arise in the submucosa as a rounded tumor not involving either the mucosa or the muscularis but pushing the mucosa toward the lumen and the muscularis toward the serosa forming a visible and palpable circumscribed mass. The exact nature of these tumors is not recognized until after pathologic examination.

Fig. 53a.—Pedunculated carcinoma of the stomach.

not produce obstruction of the gastric outlet by projecting into the pylorus and even the duodenum. They are pedunculated adenomatous outgrowths of the mucosa and contain all the tissues of that portion of the gastric wall. They may be single or multiple, small or large, the largest (in our series) being 8 cm. and the smallest 6 mm. in diameter. Polyps may be either benign or malignant and the diagnosis can be determined with accuracy only on pathologic examination.

Epitheliomas or malignant tumors composed of squamous epithelium are extremely rare in the stomach.

Myomas are characterized by localized well demarcated enlargements of the muscle of the gastric wall. These must be differentiated from the diffuse muscular hyper-

trophy not infrequently seen in association with pyloric obstruction. It is the function of the surgical pathologist to determine which myomas, fibromyomas and fibromas also are sarcomatous.

Idenomas or tumors composed of differentiated glandular cells arranged in acinar form are relatively rare. A tumor of one of these types may be associated with, but may have no apparent relation to, carcinoma and it may project into the gastric cavity producing a polypoid mass.

Simple *cysts* forming tumors and polycystic tumors lined by differential columnar epithelium and containing mucoid or clear fluid are extremely rare. Dermoid or cystic tumors lined by squamous epithelium and containing disintegrating fat and sometimes hair are rare. The largest tumor of this type encountered at the Mayo Clinic weighed 1000 Gm.

The majority of *diverticula* are found as

masses near the pylorus and are not recognized positively until after resection. They are invaginations of the mucosa and submucosa through the muscularis" and as such are not true tumors although they may often confuse the diagnosis.

Foreign bodies may often be mistaken for tumors of the stomach, and operation may be advised. Hair balls (trichobezoars) and masses of retained remnants of ingested fruits (phytobezoars) are occasionally encountered.

CARCINOMA OF THE STOMACH

It has been estimated that 38 000 persons die annually in the United States from carcinoma of the stomach, one of the most seri-

ous in symptoms and clinical course a benign ulcer even by responding temporarily to medical treatment.

There is great variability in the manifestations of the disease. Gastric carcinoma ulcerating or otherwise may temporarily simulate peptic ulcer especially at the outset. Later, however, the carcinomatous nature of the lesion or the transformation of a benign into a carcinomatous ulcer may be suggested symptomatically by one of the following: (1) disappearance of intermittency of the exacerbation with substitution of a remittent or continuous clinical course, (2) irregularity, diminution or disappearance of the "pain-food-ease" sequence, (3) substitution of the usual pain or distress by a dull

Fig. 536.—Polypoid carcinoma of the posterior wall of the stomach.

ous of all malignant processes. Men are affected about three times as often as women. The majority of persons who have such malignant tumors are seen when they are between the ages of forty and sixty years, the average age being fifty-five years.

Symptomatology.—The symptoms of carcinoma of the stomach are determined partly by the site of the growth, by its extent and by the degree of motor impairment which it causes. A lesion confined to the pars media at the lesser curvature or one that lies on the anterior or posterior wall (Fig. 536) may be silent until well advanced, a tumor near either the pyloric or the cardiac orifice may cause marked obstruction before giving any other evidence of its presence, a small ulcerating especially a crateriform lesion may

ache more or less constant and eventually aggravated rather than eased by alimentation and (4) loss of appetite and onset of nausea, both of which may ensue even in the presence of adequate gastric acidity.

Objectively, a diminution of the gastric acidity, a disturbance of motor function, the onset of anemia in the absence of gross hemorrhage and the appearance, increase or persistence of occult blood in the gastric content and feces are significant.

Epigastric distress occurs in about 90 per cent of cases when carcinoma of the stomach has been fairly well established or has become advanced. Vomiting is experienced in from 60 to 80 per cent of such cases. Gaseous eructation usually is found and in many instances becomes gradually more marked.

Loss of appetite and loss of weight frequently are complained of and may occur early in the disease. Bleeding from the stomach is evidenced by vomiting of blood or the passage of black, tarry stools, but this is much less common in carcinoma than in ulcer. In about two thirds of the cases there is a definitely demonstrable mass in the upper part of the abdomen (Fig. 537).

Diagnosis.—It is an accepted fact that the chief basis of successful treatment of carcinoma of the stomach is early diagnosis. Factors essential to more prompt recognition of this malignant condition are: (1) physical examination at stated intervals by a competent physician, (2) the attaching of proper significance to indigestion of an un-

examination (roentgenologic) by which the early, symptomless lesion can be detected is easily overlooked. Too often the symptoms become so bizarre or the disease so far advanced that it has passed the curable stage before it can be recognized. For these various reasons, the patient often deprives himself of the opportunity for cure by a timely operation.

The important points usually enumerated for diagnosis of carcinoma of the stomach are as follows. (1) onset, in a person at the so-called "cancer age" (from forty to sixty years), of dyspepsia, associated with anorexia, pain and vomiting which has resisted treatment for three months. (2) steady loss of weight and (3) progressive anemia

Fig 537—Scirrhous carcinoma of the antrum of the stomach

explainable or persistent nature, which may have begun insidiously or abruptly after the fourth decade of life, (3) the seeking of medical advice promptly under the circumstances, (4) employment of all available laboratory methods of diagnosis, of which roentgenology is by far the most important and is essential to the detection of carcinoma in its earliest stages or in its obscure form, and (5) closest cooperation between clinician, roentgenologist, surgeon and pathologist.

The middle-aged layman too frequently delays in seeking medical advice for digestive disturbances, and the early clinical signs of carcinoma of the stomach are often so indefinite that the necessity of the only

These represent symptoms, in most instances, of advanced carcinoma, and if the patient is to receive the benefit of surgical removal of the malignant process, the disease should be recognized earlier.

It cannot be too strongly emphasized, therefore, that if there is any persistent disturbance in gastric function, particularly if it is of recent appearance, mild or severe, and if the history reveals any irregular or atypical syndrome of ulcer or a certain departure from normal results in an analysis of the gastric content or any tendency to gastric retention or obstruction, the possibility of carcinoma always must be kept in mind, and an experienced physician and roentgenologist must be consulted. It is an

unfortunate paradox that although the disease can be identified readily in its early stages this is rarely done.

The question arises as to whether in the diagnosis of carcinoma of the stomach roentgenologic and gastroscopic methods can supersede all others. The recent development of gastroscopy has added much to the knowledge of both benign and malignant lesions of the stomach and has shown that it is possible to make visible these small lesions which are so situated that even the expert roentgenologist may not be able to detect them either roentgenographically or roentgenoscopically.

The experienced clinician will not delay until definite symptoms and signs appear but on suspicion will demand if necessary repeated roentgenoscopic examinations and if advisable gastroscopic examination. He will not be deluded into believing that a patient cannot have a carcinoma of the stomach when he is apparently in good health and when values for gastric acids are normal weight has not been lost and a tumor is not palpable.

It has been suggested that if there is doubt from its roentgenologic appearance as to whether a lesion is malignant or not the differential diagnosis can be made by observing the results of medical care if the condition is relieved it may be assumed that the lesion is benign. McVicar and others found however that this might give an erroneous impression since the patient temporarily may respond satisfactorily to medical treatment. The clinician therefore is primarily concerned with the indications for exploration and with the probabilities of the removal of the growth. The latter offers the patient his only chance for cure. The surgeon is interested to learn about the degree of extension of the growth, the possibility of its complete removal and the grade of malignancy as defined by Broders. The surgeon also wishes to know what degree of palliation may be afforded the patient if cure is not possible, which of the various procedures that have been evolved to bring about either cure or palliation is indicated in a particular case and how great will be the risk of operation.

Gastric carcinoma must always be distinguished from such intrinsic lesions as gas-

tric ulcer and benign tumor from such conditions as chronic gastritis, gastric syphilis and gastric tuberculosis and from phytobezoars especially when they are associated with large crater like ulcers. Extrinsic lesions to be excluded are diseases of the pancreas, gallbladder and colon, some degenerative lesions of the kidneys, lungs, liver and suprarenal glands, digestive disturbances resulting from toxemia, secretory dysfunction, chronic glomerular nephritis and diffuse nephritis and pernicious anemia.

Indications for Treatment—It should always be kept in mind that death surely will occur within a period of months if the disease is not interrupted in its course. The purpose of treatment therefore is two fold: (1) to effect cure if possible or (2) to prolong life and assure the patient a minimum of suffering. Non surgical methods including radiation are purely symptomatic or palliative in effect.

Cure of carcinoma of the stomach by surgical treatment has been accomplished in a sufficient number of cases to remove any doubt that it is possible under certain circumstances. In addition to this ever present possibility surgical treatment properly applied in many of the less favorable cases will prolong life, will protect the patient against disagreeable complications and in many respects will fully justify itself.

When a diagnosis of tumor of the stomach has been made or a lesion is demonstrated which may be malignant the indications for its treatment present many important considerations. A fundamental principle is that every patient is entitled to exploration unless the disease can be proved to be incurable and unless it is perfectly obvious that a palliative procedure also would be unwise. This means that unless a definite metastasis can be demonstrated unless the fluoroscope reveals involvement of the cord or unless both roentgenologist and clinician realize that the lesion is unresectable surgical exploration of the growth is warranted. The surgeon will base his advice on the standpoint that cure may sometimes be brought about even in cases in which on examination the disease appears too far advanced for cure.

The question of metastasis of carcinoma of the stomach is of first importance in de-

termining whether or not surgical treatment is indicated. Fortunately, early, distant metastasis occurs in situations in which it can be detected by careful examination; when it is found, any prospects of cure are dispelled, but when it is overlooked, unnecessary exploration may be made. The most common sites for signs of distant metastasis are the supraclavicular lymph nodes and the peritoneum of the rectal shelf. Positive findings by palpation or by histologic examination of a lymph node follow-

Pain of gastric carcinoma has significance in respect to operability. Although distress is a common symptom, severe pain is rare and is usually significant of extragastric involvement, from penetration or perforation by the growth. Pain, therefore, is an unfavorable sign and probably indicates that the possibilities are remote for eradication of the disease.

On the basis of what has been said in the foregoing, exploration is advised in more than half of the cases of malignancy of the

Fig 598—Billroth I, von Haberer-Finney operation. The end of the stomach is anastomosed to the side of the duodenum.

ing biopsy, in either site, denote incurability but not always undesirability of exploration.

Careful examination of the peritoneum of Douglas' pouch should be made, for this may be the site not only of early but also of the only metastasis. Rectal examination of the patient who has carcinoma of the stomach never should be omitted.

The more common adjacent sites of metastasis are the liver and the umbilicus, and when they are demonstrable clinically, operation is contraindicated, regardless of other circumstances.

stomach, and when this is carried out, it is found that the growth can be removed in about 45 per cent of the cases, so explored.

The indications for operation include selection of the optimal time. The patient should be in the best condition possible, and for him to be put in this condition frequently requires hospitalization, so that the effects of obstruction can be overcome, dehydration can be counter-balanced, the stomach can be cleansed and the nutritional state and anemia can be improved as much as is reasonably possible. Correction of the effects of

the obstruction will reduce congestion in the gastric walls and often will improve the condition of the tissues so that more satisfactory and safer suture is possible.

Surgical Treatment—Once it has been decided that exploration at least, is indicated examination of the growth itself is of utmost importance. The extent of extragastric involvement should be determined and unless it is clearly apparent that the disease

filtrating growth may be clearly inoperable whereas a similar growth in a case in which the patient is asthenic and the stomach is prolapsed may be operable. For an extremely large ulcerating or colloid carcinoma total gastrectomy or nearly total gastrectomy is justifiable if the stomach can be mobilized whereas these operations would not be reasonable if the stomach were small and firmly fixed.

Fig. 539.—Posterior anastomosis. The end of the stomach is anastomosed to the side of the jejunum following partial gastrectomy for carcinoma of the stomach.

is not eradicable the lesser peritoneal cavity should be widely opened through the gastrocolic omentum to allow inspection of the extent and the character of any posterior perforation or attachments.

Decision as to whether resection is justifiable or not depends also to a considerable extent on the type of stomach in which the growth has occurred. In those cases in which the stomach is small and highly innervated

If it is obvious that the lesion is too wide spread to be removed the distressing situation which arises from an erroneous diagnosis should always be guarded against by removal of tissue for microscopic examination.

If resection seems to be justifiable there are many methods by which it may be accomplished and partial gastrectomy has been developed to a point at which the dan-

gers which were commonly fatal in the past have been largely eliminated. As far as general principles are concerned the growth should be removed as widely as possible, gastrointestinal continuity should be re-established without undue tension and the mechanical function should be perfect.

The methods conform to one or the other of two types: direct anastomosis between the end of the stomach and the duodenum (Fig. 538) or closure of the duodenal stump and union of the remaining portion of the stomach with the first loop of the jejunum

the duodenojejunal angle by a small enteroanastomosis; this prevents retrograde distention of the duodenum and obviates the possibility of danger from that source.

The advances made in recent years are illustrated in the increasing frequency with which total gastrectomy is performed, since this operation is now being done with considerably less risk than formerly (Fig. 541). The transthoracic approach to high lying malignant lesions which encroach on the esophagus has distinct advantages. The percentage of cures following the operation un-

Fig. 540—Position occupied by the stomach and jejunum after extensive gastric resection and restoration of the continuity by an anterior end-to-side anastomosis with enteroanastomosis.

Anastomosis between the end of the stomach (Fig. 539) and the side of the jejunum has attained the greatest favor largely because it consumes less time than the Billroth II procedure. The gastrojejunal anastomosis can be made either behind the colon or in front of it (Fig. 540). The posterior method can be used in many cases without difficulty, but when after extensive resection only a small segment of stomach is left it is simpler, safer and less likely to give rise to complications to bring a long loop of jejunum up in front of the colon and to attach the loop to the end of the stomach. When this operation is completed the two loops of jejunum should be united opposite

doubtedly will be low chiefly for the reason that the operation usually is indicated only when the disease is advanced. This fact together with the relatively high risk of the operation would indicate that only in well selected cases is the operation advisable.

Gastroenterostomy occasionally is useful when it is performed preliminary to resection. Apparently, however, the indications for its use in the treatment of carcinoma are becoming less and less. In the first place if gastroenterostomy can be satisfactorily performed the disease cannot have extended very far toward the cardia in which case at least exclusion of the growth probably could be effected or even palliative resection

could be performed. Experience has shown that when the disease is very extensive and gastroenterostomy is attempted the surgeon may be forced to place the stoma in an unsatisfactory situation so that it fails in its purpose of providing adequate drainage; moreover the risk of operation is considerable since immediate improvement is not realized to as nearly a complete degree as when obstruction is satisfactorily relieved. A further objection to gastroenterostomy alone is that even when it fulfills its purpose of relieving obstruction if the disease extends the gastroenteric stoma is prone to become involved in the malignant process and obstruction recurs.

course to gastric lavage when indicated may be effective in maintaining a good state of nutrition and the physical comfort of the patient for a considerable period.

If obstruction is marked frequent aspiration of the gastric content will prove to be of distinct benefit in improving the general condition of the patient and will assist materially in the technical surgical procedure by presenting for the surgeon's consideration a stomach that has been cleansed thoroughly of all retained material. The diet should be liquid or semifluid and not too much should be given at one time.

The value of radiation for irremovable malignant processes in the stomach, as well

Fig. 541.—Scirrhous carcinoma involving the entire stomach for which total gastrectomy was performed.

Palliative Treatment—Increasing experience confirms the early observation made by W. J. Mayo that great palliation frequently could be obtained in certain types of gastric carcinoma. The various palliative measures for carcinoma of the stomach include both medical and surgical treatment. The medical treatment has not been given sufficient emphasis by members of the medical profession because the merit of any method usually has been judged solely on the basis of permanency of cure. Due consideration has not been given the effect of such methods in the control of distressing symptoms.

Intelligent choice and use of a suitable dietary regimen, sedatives, opiates, tonics, and digestants, rectal alimentation and re-

as its merit as a postoperative measure has not been established because of the indefinite results which have followed such treatments. Surgical methods of palliation include gastric resection, exclusion of the growth, gastroenterostomy and jejunostomy.

Results of Treatment—The mortality following operations for carcinoma of the stomach can be markedly lowered by scrupulous attention to preoperative treatment. If the physician cooperates with the surgeon in maintaining good care after the operation the risk is reduced to a minimum.

If operation for gastric carcinoma is carried out along the general lines that have been outlined, the rate of operability is approximately 45 per cent. The possibilities of cure in cases of carcinoma of the stomach

are shown by the fact that of several series of consecutive cases in which resection was carried out an average of 90 per cent of the patients are alive and apparently well three years after operation regardless of the extent of the disease at the time of resection. If those cases are selected in which the disease is still confined to the stomach that is in which there is no involvement of lymphatic structures 49 per cent of the patients are alive and apparently well three years after resection. A low mortality rate for operations is dependent on a number of factors the chief of which are (1) good judgment in deciding on the possibility of cure or worthwhile palliation (2) adequate preparation of the patient for operation (3) meticulous care and skill in carrying out all the details of the operation and (4) adequate postoperative care. If these essentials can be met hospital mortality rates for gastric resection for carcinoma of the stomach of less than 10 per cent are being reported.

BENIGN TUMORS

The actual proportion of benign tumors to malignant tumors of the stomach is 1:200 and benign tumors form 1.3 per cent of all gastric growths. They present a wide variety of histologic types adenomatous and fibroadenomatous polyps fibromas myomas hemangiomas dermoid cysts papillomas polypoid masses neurogenic tumors leiomyomas and alipomas.

Benign tumors in themselves are symptomless unless they are complicated by bleeding or ulceration or unless because of their size and extent they cause intermittent obstruction of the pylorus or interference with gastric motility and secretion. In 25 per cent of cases symptoms of pyloric obstruction are present. Hemorrhage from ulceration of the tumors is a more common complication and may be severe. The most frequent and most important sign of benign tumor of the stomach is anemia. This is usually of the secondary type but in cases of long standing the anemia may progress to a point suggestive of anemia of the primary type. In all of the cases of this type seen by the writer the blood picture returned to normal after removal of the polyps. Another interesting observation in all cases of polyp uncomplicated by other gastric lesions is the

absence of free hydrochloric acid from the gastric content. This tends to obscure still further the differential diagnosis of pernicious anemia, gastric carcinoma and benign tumors. In some cases the only physical finding suggestive of benign tumor was that the tumor was large enough to be palpable. Usually however benign tumors are relatively symptomless and when small not eroded not too near the pylorus and not associated with other lesions are rarely diagnosed clinically except by roentgenologic examination.

Roentgenologically the condition is more suggestive than diagnostic and with the ex-

Fig. 512.—Benign tumor of the stomach

ception of gastric polyposis with characteristic mottling of the shadow to identify the type of tumor is not possible. (Fig. 512) Moore stated that in general a benign tumor produces a circumscribed and punched out filling defect usually on the gastric walls leaving the curvatures regular and plant. Although the rugae are obliterated from the immediate area of the tumor just as is true in the presence of inflammatory and malignant lesions the rugae which surround the benign tumor are more nearly normal in arrangement and distribution. Little disturbance in peristalsis is noted and there is no night incontinence or other evidence of spasm.

As in carcinoma and sarcoma of the stomach, treatment for benign tumors is by surgical removal. Most benign tumors, partic-

ularly the polyps, can be removed by amputation at the pedicle, accomplished by cauterization (Fig. 543). Occasionally, a pedunculated polyp will become invaginated into the

duodenum, and probably a diagnosis of tumor of the duodenum is made. This is an essential point in determining the prognosis

Fig. 543.—Cauterizing knife incision for multiple gastric papillomas

Fig. 544.—Sarcoma of the stomach

ularly the polyps, can be removed by amputation at the pedicle, accomplished by cauterization (Fig. 543). Occasionally, a pedunculated polyp will become invaginated into the

and is involved in the question as to whether or not the tumor may be potentially malignant, as may be the case if the growth originates in the stomach.

MISCELLANEOUS

Surgical intervention rarely is indicated for diverticula. Simple gastrotomy for removal of a bezoar, or hair ball usually is followed by complete relief.

Sarcoma of the stomach (Fig 544) is found rarely and is definitely diagnosed only on operation and histopathologic examination. Operation usually is advised because of a diagnosis of carcinoma. The primary purpose of treatment of sarcoma of the stomach is removal of the growth. Various procedures have been carried out in such cases. Of a series of 53 cases in which exploration was made in 15 the growth was inoperable in 27 the Billroth II type of resection was performed in 6 sleeve resection was carried out in 3 the tumor was excised and in 2 palliative gastroenterostomy was performed. The methods of resection are essentially the same as those employed for resection of carcinoma. In cases of sarcoma however there are more frequent indications for restoring gastrointestinal continuity by antecolic end to side enteroanastomosis. More extensive resection can be accomplished in cases of sarcoma than in cases of carcinoma because of the sharper demarcation of the growth in sarcoma.

Irradiation by roentgen rays only was used after operation for sarcoma of the stomach in 14 cases. The sarcomas of the stomach which are most favorable for treatment by roentgen rays are lymphosarcomas and if they could be diagnosed sufficiently early they might be cured by irradiation alone. The basis for the effectiveness of this treatment is that the lymphocytes are more sensitive to the rays than are any other cells of the body.

The mortality of resection for sarcoma will parallel that of carcinoma. The prospects of cure appear to be greater if radiation is employed in addition to surgical removal.

SYPHILIS OF THE STOMACH

Definition—Syphilis of the stomach is a tertiary lesion characterized anatomically by a broad plaque-like thickening of the gastric wall with superficial ulceration of the mucosa. The symptoms are generally referable to the obstructive and contractural lesions which frequently result from cicatricial changes of the specific granulation tissue.

Etiological Considerations—The disease occurs in hereditary as well as in acquired cases. The factors that influence the localization of the *Spirochaeta pallida* in the stomach are not known. Although quite uncommon gastric syphilis is by no means as rare as formerly supposed. Its comparative incidence is probably 1 per cent of significant organic lesions of the stomach. The average interval between the appearance of the primary lesion and the onset of gastric symptoms is about ten years. The third and fourth decades are predilected. The affection is twice as common in the male as in the female.

Pathology—Many different types of lesions have been described in connection with gastric syphilis. The only lesion which the writer has encountered or seen actually depicted is a broad rather flat thickening of the gastric wall which tends to be associated with superficial ulceration. A true gummy tumor exhibiting gross caseation such as occurs in the liver for instance has not been observed in the stomach. Isolated round calloused ulcers which penetrate deeply and are frequently reported as syphilitic are

almost invariably peptic ulcers in luetic patients

The thickening of the gastric wall is in the nature of a plaque like proliferate or infiltrate which is of variable length and width. Frequently the thickening occupies the entire circumference of the stomach in which event stenosis results. Only rarely is the entire stomach involved producing the leather bottle type of contracture. The prepyloric and mid portions are sites of predilection for encircling lesions. At times there are two or more thickened areas separated from one another by relatively healthy gastric wall. The proliferated tissue involves chiefly the submucosa which occupies three fourths or more of the thickness of the gastric wall. The proliferate forms a flat elevation the central portions of which tend to undergo ulceration. A single large denudation may involve most of the elevation or the defects may be multiple and separated by islands of intact mucosa. The ulcers are of irregular shape with serpiginous outlines and are quite superficial. Since the erosion occurs at the summit of the proliferate the floor of the ulcer is well above the surface of the normal mucosa in contrast to the relationships which obtain in peptic ulcer.

Microscopically the thickening in the active stage consists of specific granulation tissue including particularly a pyovascularitis infiltrates of round and plasma cells and not infrequently milium gummas. In the advanced state cicatricial tissue is chiefly in evidence. The involvement is primarily and predominantly submucous with extension to the adjacent layers. The mucosa becomes the seat of a non specific atrophic gastritis. The stomach is generally free from perigastric adhesions the latter when present being the result of secondary infection. The neighboring lymph glands are only moderately enlarged and succulent. The most frequent associated syphilitic lesion observed by the surgeon is a gummatous hepatitis or hepatic lobatum. Only rarely are specific lesions encountered in the intestine or spleen.

Symptomatology—The gastric manifestations are referable generally to increasing motor impairment. Discomfort gradually develops shortly or immediately after meals. Vomiting which appears relatively early in the illness usually affords relief and ab-

stinence from solid and coarse foods ameliorates the suffering. At times the rhythm of the postprandial pain bears a resemblance to that of ulcer but is not nearly so constant. Anorexia is generally absent in fact the appetite is good but starvation may result early because of sitophobia.

The discomfort and vomiting tend to progress slowly. The patient reduces the diet voluntarily until all but liquids are banished. In the advanced stages the symptoms are due to a reduction in the capacity of the stomach. By that time there is considerable loss of weight but no significant degree of anemia. Profuse hemorrhage or perforation is quite rare. In cases of prolonged starvation deficiency diseases may develop.

Emaciation is the only outstanding physical sign. Usually no mass is palpable. Gastric analysis demonstrates the presence of achlorhydria and less frequently of hypochlorhydria. Occult blood although frequently present in the stools is not uncommonly absent. The roentgenogram discloses a circumscribed and occasionally a diffuse smooth contractural lesion generally symmetrical with stiffening of the involved portions of the gastric wall. The Wassermann test of the blood is only exceptionally negative. Clinical evidences of lues other than those pertaining to the stomach may be present.

The advent of gastroscopy has aided in the diagnosis of syphilis of the stomach. Moutier has given a complete gastroscopic description of gastric syphilis. He describes tumor formations gummas multiple ulceration and scarring hemorrhagic gastritis and atresia (limitis plastica). Atrophic hypertrophic and mixed gastritis changes on the basis of syphilis have been recorded by others.

Diagnosis—The presence of syphilis of the stomach is to be considered whenever an atypical case of gastric disorder is presented. The combination of symptoms of a benign lesion from the standpoint of duration roentgenographic evidence and acidity corresponding to those of malignant disease serves to suggest the presence of gastric lues. A positive Wassermann reaction in a patient with organic disease of the stomach should likewise lead to the suspicion of a specific etiology. The chief difficulty lies in distin-

guishing gastric lues from carcinoma. In favor of the former are the age of the patient, the duration of the illness, the lack of significant anemia in spite of emaciation, a smooth contractural deformity in the roentgenogram without the intrusion into the lumen of a growth, and the serological and clinical evidence of syphilis. A disproportion between the extensive involvement of the stomach roentgenologically and the comparatively good physical condition of the patient favors a luetic etiology. Of value also in the diagnosis is the therapeutic test provided an advanced obstructive lesion does not exist. The results of antiluetic treatment can be followed roentgenologically as well as clinically.

Often the differential diagnosis must be made at operation. Here the surgeon will generally be impressed by the fact that he is dealing with a lesion which is unlike any gastric carcinoma or peptic ulcer he has encountered. This alone should suggest the possibility of lues. The granulomatous proliferate unlike that of carcinoma is soft and succulent and presents the characteristics described under pathology. A biopsy specimen removed at operation is generally reported as chronic inflammatory tissue and serves to rule out carcinoma. The only gastric affection other than carcinoma which requires serious attention in the differential diagnosis of syphilis of the stomach is a prepyloric ulcer with obstruction. Corrosive poisoning, extensive perigastritis, subacute or chronic phlegmonous gastritis, lymphogranuloma (Hodgkin's) and lymphosarcoma occasionally enter into consideration.

Treatment.—A knowledge of syphilis of the stomach is of practical import because the disease lends itself admirably to treatment. Specific therapy is given credit for numerous complete cures chiefly by roentgenologists and internists. There is no question but that medical treatment should be attempted wherever mechanical relief of an obstruction is not urgent. Many cases undoubtedly yield to medical management. However, since the proliferation tends to heal by cicatrization, cure of the lesion frequently results in strictures which sooner or later necessitate operative intervention. In cases of high grade motor insufficiency a therapeutic test is not warranted as the ob-

struction generally fails to recede and the gravity of a subsequent operation is increased as a result of the delay. The aim should be to perform the simplest type of anastomotic operation. Gastroenterostomy suffices in a large percentage of cases. Care should be exercised in choosing healthy gastric wall for the site of the stoma. When the lesion is extensive subtotal gastrectomy is required. Total gastrectomy is rarely indicated. Antiluetic treatment is to be administered energetically in the preoperative as well as postoperative stages. Following extensive resections an antineuritic regimen is instituted.

NON ULCERATIVE LESIONS OF THE DUODENUM

This section deals with pathologic entities and lesions of the duodenum other than ulcer. Surgical treatment is required in some cases; in others it is decidedly contraindicated. The differential diagnosis is often dif-

ficult and confusing. The combined judgment of internist, roentgenologist and surgeon, working as a team and having a combined mature experience, is essential in dealing with these patients if the correct therapy is to be given. In many cases the help and cooperation of the psychiatrist is needed in the study and treatment.

In preparing this section the writer, who for many years has been interested in duodenal pathology, has utilized the very abundant material of the Vanderbilt Clinic and the Presbyterian Hospital of Columbia University. This clinic is the out patient department of six affiliated institutions. All patients going to the wards of these hospitals are studied, admitted, discharged and followed to the Vanderbilt Clinic, and on admission as a patient, the history, physical examination and laboratory findings become

a unit record, to go with him to whichever of the affiliated institutions he may be admitted subsequently. In this way continuous and continuing records of inestimable value have accumulated far superior to the old fashioned bound volumes containing isolated records of each admission of a patient in each of several institutions for they contain not only the data of each admission, but also follow up notes of the interval between admissions.

The classification of the entities and lesions of the duodenum, with the number of cases under each heading, is given in Table 7.

Before dealing with the separate entities it is important to discuss certain fundamental factors related to duodenal lesions. Ivy has discussed and summarized these and the following is based on his article on the physiology of the duodenum.¹

Functions of the Duodenum. (1) motility, (2) secretion and (3) absorption.

1 *Motility*—(a) *Rhythmic segmentation*—to mix duodenal bile and pancreatic juice with incoming chyme. (b) peristalsis initiated by the ejection of stomach contents into the duodenum. There is considerable debate as to whether the peristaltic wave from the stomach passes in continuity over the pylorus on to the duodenum. It has been shown by Ivy that during hunger motility of the stomach, the duodenum shows contractions synchronous with those in the stomach with the exception that frequently the duodenal contractions lag behind those in the stomach. He believes that hunger contractions or their effect pass from the stomach to the duodenum.

There are two points in the duodenum where there is a tendency to retention—the bulb and the lowest point of the duodenum, i. e. the junction of the second and third portions. Any pressure or angulation at these points as by a hepatoduodenocolic band over the bulb or angulation of the preacrotic portion by the overlying superior mesenteric vessels will accentuate this tendency.

The question as to how much pressure is necessary to overcome the propulsive force of duodenal contraction or peristalsis has been studied by the Dragstedts.² They showed that a circular extrinsic pressure by a light rubber band equivalent to 6 inches of water is sufficient to cause lethal acute duodenal obstruction. Considerably more pressure is required to overcome the normal propulsive force of peristalsis in the jejunum, ileum and colon. An extrinsic pressure of less than 6 inches of water is sufficient to produce partial obstruction with its associated hyperperistalsis, dilatation, nausea and vomiting.

Reversed peristalsis has been noted fluoroscopically under normal and abnormal conditions. It occurs normally in some persons at the end of a meal when strong acid chyme is being ejected into the duodenum. Ivy¹ has shown that in a dog in good health after recovering from the establishment of a Thury duodenal fistula bile is regurgitated into the stomach when acid or a mildly irritating substance is injected into the fistula. This indicates that reversed peristalsis can be produced reflexly through the celiac ganglion.

The Effect of Duodenal Stimulation on the Motor Activity of Other Parts of the Gastrointestinal Tract—Brunemeier and Carlson³ confirmed by Ivy have shown that stimulation of the duodenum inhibits the motility of the empty stomach.

Vomiting—Luckhardt, Phillips and Carlson⁴ corroborated by subsequent observers showed that vomiting is more readily produced by duodenal than by gastric irritation. Ivy¹ experimenting with a duodenal balloon was able to inhibit the vomiting impulse caused by pharyngeal and gastric irritation but could not control the impulse to vomit when the duodenum was irritated because of the more sudden and violent impulse.

Colon—Ivy and McIlvaine⁵ observed that in dogs with a Thury fistula the colon was responsive to duodenal stimulation. When acid or other stimulants were first applied to the Thury fistula of the duodenum either defecation or vomiting and sometimes both resulted.

Hicough—Ivy¹ has observed hicough to occur repeatedly on sudden distention of a duodenal Thiry fistula in dogs.

Bile Tract—It has been demonstrated since Meltzer's early experiments in 1917 and corroborated subsequently by such observers as Lyons, Roux and Graham, that stimulation of the duodenal mucosa plays a fundamental role in the flow of bile from the gall bladder and ducts.

2 Secretion—By establishing a Thiry fistula of the duodenum the rate of secretion, its character and content and response to various stimuli can be studied. Ivy² has summarized these phases in his discussion of the physiology of the duodenum. He finds no evidence that the duodenum excretes any specific substance or has any role as an excretory organ.

3 Absorption—It is known from experimental study that the duodenum rapidly absorbs water, glucose, alcohol and crystalline salts. Probably little absorption of food occurs in normal digestion because of the rapid passage of gastric contents through the duodenum.

In acute duodenal obstruction experimentally produced it has been shown that toxic substances are absorbed through the duodenal mucosa. Whether absorption of poisonous products takes place in chronic duodenal dilatation or obstruction is questionable. The writer has seen cases of long-standing mechanical duodenal obstruction in which there was no evidence of absorption of toxic substances as long as the obstruction was not complete.

Innervation—1 *Efferent*—Data regarding the exact efferent innervation of the duodenum are not satisfactory. Ivy³ teaches that the vagi and the splanchnic nerves probably carry both motor and inhibitory fibers to the duodenum, the vagi being predominantly motor and the splanchnics predominantly inhibitory.

2 *Afferent*—The exact afferent nerve paths from the duodenum have not been demonstrated but whatever the afferent nerve routes there is no question now regarding the definite subjective sensations produced by duodenal stimulation or irritation.

Ivy⁴ and his pupils, experimenting on themselves by means of a balloon placed in the duodenum, have described their symptoms accurately. Nausea is the most frequent symptom and can be distinguished from the pharyngeal and gastric nausea by a sudden violent impulse to vomit. Pain is next in frequency. Either distention or spasm of the duodenum causes it. On distending the balloon when it was in the third portion Ivy referred the pain to the midline from 3 to 5 cm. above the umbilicus. When the balloon was withdrawn pain was felt beneath the liver on the right side. On two occasions a sore spot persisted over the clavicle at the junction of the outer and middle thirds. Other symptoms less constantly observed were uneasiness, faintness, dizziness, chilliness and dragging and aching sensations. Pallor was a frequent physical sign. It was observed that after removal of the balloon no "after image"—persistent sensation of the balloon or distention in the duodenum—remained. Frontal headache was also observed as an accompanying and persistent symptom.

Inhibitory Factors to Motility—The Dmstedts⁵ have shown that the propulsive force of duodenal peristalsis is inhibited by much less force than that

in other parts of the intestinal tract. This may explain how the inhibitory impulses coming through the splanchnic nerves and controlled by psychogenic factors may from time to time result in a dilatation and duodenal delay in the cases in which under ordinary conditions slight obstruction or angulation produces no disturbance in the propulsive efficiency of the duodenum.

With these physiologic and experimental points in mind, it must be emphasized that in the large group of patients showing duodenal dilatation and duodenal delay, whether they be in the group with definite obstruction demonstrable by barium study, or on the operating table, or at autopsy, or in the group with no demonstrable obstruction, or in the group of patients with duodenal diverticulum with barium retention or evidences of inflammation, the factors of duodenal irritation and abnormal duodenal stimulation give rise to symptoms and signs analogous to those produced experimentally in animals or man. These common symptoms of nausea and vomiting, upper abdominal pain, distress, and distention, dizziness and headache, and vasomotor disturbances, as shown by pallor and low blood pressure, are seen in so many lesions of the upper gastrointestinal tract and bile passages and pancreas, both organic and functional that great confusion occurs in their diagnosis and therapy. This accounts for the fact that many patients with surgically remediable organic lesions have been treated for years for so-called "nervous indigestion", and on the other hand in many of the patients with no organic lesions, operation is carried out, often with unnecessary and ineffective short-circuiting procedures, resulting in intensified symptoms and a worse neurosis than before operation. The two most common mistakes in dealing with these patients are (1) failure by the competent experienced internist, surgeon and roentgenologist—working as a team—to study the duodenum carefully with barium fluoroscopy in order to determine the presence or absence of organic pathology and (2) in the patients in whom no obstruction or other organic lesion is found to discover and deal adequately with the underlying cause of the neurosis, whether it is fear, anxiety or an associated debilitating factor in some other part of the organism. Many of the patients

in this group have deep-seated often subconscious psychogenic etiologic factors that require the skill patience and time of an experienced psychiatrist for discovery and correction. Failure to recognize that these psychogenic factors play a dominant role in the cases of chronic duodenal stasis or duodenal dilatation is most noticeable in practically all of the studies thus far published. The failure in therapy surgical and medical in these cases can be largely explained by the failure to recognize and deal with the psychogenic cause so frequently present.

The writer is quite certain after studying the follow up notes in the large series of case reports available at the Vanderbilt Clinic and Presbyterian Hospital—many of them covering a period of ten years or more—that the results of therapy hitherto published are inaccurate. If followed for a period of years the great majority of the patients especially those without organic obstruction show recurrent symptoms whatever therapy is used. This is especially true if the causes of fear anxiety or worry are not removed.

FUNCTIONAL AFFECTIONS OF THE DUODENUM

Etiology—In these patients an anxiety neurosis is practically always the etiologic factor.

Symptomatology—The symptoms are those referred to in the preceding paragraph. Nausea and vomiting upper abdominal pain distress distention dizziness headache and vasomotor disturbances are commonly present.

Diagnosis—The diagnosis is based on finding the aforementioned symptoms in the absence of demonstrable obstruction.

Treatment—The patient who does not have a demonstrable organic obstruction should be treated conservatively for surgical treatment in the majority of these cases merely adds to the psychogenic factor. The method of therapy now in use at the Presbyterian Hospital which has turned over the attacks was devised by Dr. Amsterdam Crump and is used by him with excellent results in many of the cases. It is as follows:

- 1 Lavage at bedtime allowing a twelve hour rest of the stomach without any food.
- 2 Ulcer type of diet with pureed food.

- 3 Feedings every two hours followed one hour later by the administration of alkalis.

- 4 Flexion exercises after the first week or so to increase the intra abdominal tension and aid the weak muscle tone of both stomach and duodenum.

- 5 Oil retention enemas for patients in whom constipation is associated with pressure on the duodenum or the colon.

The author wishes to stress the absolute necessity of discovering and properly treating the underlying factor of anxiety in these cases. Unless this is done the patients will remain recurrent invalids and a burden to themselves and their families. This requires the training and time—in some cases weeks—of a psychiatrist or physician interested in the psychoanalysis and psychotherapy of these patients. The majority of the anxiety factors are not Freudian in character and for this reason may not interest some psychoanalysts. In many of our cases the social service worker was the one to discover the underlying anxiety factor.

It is interesting but pathetic to note the utter lack of appreciation of this phase of therapy on the part of some surgeons who operate on and some gastroenterologists who lavage these patients with the result that there are recurrent symptoms and the patients become more neurotic.

CONGENITAL DEFECTS OF THE DUODENUM

- 1 *Congenital atresia* or congenital stenosis of the duodenum is a lesion found in the early hours or days after birth and is usually an autopsy finding. It is fortunately rare and it is irremediable unless the stricture is limited to a narrow area in the duodenum. Donovan¹⁰ has operated successfully on 4 infants with stenosis of the duodenum at the Babies Hospital New York.

- 2 *Duodenum mobile and duodenum inversum* consist of variations from the normal in the duodenal attachments and in the direction and length of one or more of the curves of the four divisions or portions of the duodenum. They represent a group of cases that are rarely recognized by internist roentgenologist or surgeon to judge from the meager literature on the subject.

Etiology—These anomalies are the re-

sult of deviations from the normal rotation of the duodenum and fusion of the mesoduodenum to the posterior abdominal wall in the first seven weeks of fetal life.

Pathology—Depending on the amount of persisting mesoduodenum and the deviation from normal curvatures varying amounts of angulation and obstruction result. In some cases the entire duodenum may be greatly dilated if the angulation is an obstructive one while others may show no pathology other than the anomaly. The 62 cases studied by the author may be divided as follows:

Two cases associated with non rotation of the gut and persistence of the duodenal

persistence of the mesoduodenum (Fig. 545 d) 1 case with deviation of the fourth portion to the right instead of to the left (Fig. 545 e, and 549), 29 cases were unclassified and consisted largely of abnormally long second portions or second portions with abnormal curvatures (Fig. 545 f).

Symptomatology—There may be no symptoms but when they are present they consist of periodic attacks of upper abdominal pain distress distention or uneasiness associated with nausea and vomiting of large amounts of bile stained fluid if the obstruction is distal to the papilla of Vater. Bloating and belching are usually present.

Fig. 545.—Types of congenital defects of the duodenum. a Associated with non-rotation of the gut and persistence of the duodenal mesentery. b Curve to the right of the third portion. c Variation in length and deviation from the normal curvature of the third and fourth portions. d Curvature of the second portion upward and to the left. e Deviation of the fourth portion to the right instead of to the left. f Abnormally long second portion with abnormal curvature.

mesentery (Figs. 545 a and 549), 17 cases (Figs. 545 b and 547) all showing a curve to the right of the third portion (in some instances the third and fourth portions rose above the bulb; in others they crossed behind or in front of the second portion below the bulb; there was a persistent mesoduodenum in some cases none in others). 7 cases with varying length and deviation from normal curvature of the third and fourth portions and a variable amount of persistence of the mesoduodenum (Fig. 545 c), 6 cases with curvature of the second portion upward and to the left and a variable

constipation is present in the majority of the patients and they are chronic dyspeptics and cathartic users.

Physical Signs—There may be no physical signs. In some a sense of fullness in the upper right quadrant and to the left of the umbilicus with a splashing sound on palpation can be elicited when the duodenum is dilated. There is usually diffuse upper abdominal tenderness. There is frequently an associated visceroptosis.

Diagnosis—The one diagnostic measure and a *quasi non* is the barium meal fluoroscope and roentgen films. This study must

be made by an experienced roentgenologist, with the patient in several positions, and must be thorough and, if necessary, repeated several times. X-ray studies will differenti-

Fig 516—Congenital defect of the duodenum associated with non rotation of the gut.

ate these lesions from gastric and duodenal ulcer and diseases of the gallbladder, the two conditions most frequently confused with duodenal dilatation.

obstruction. If there is demonstrable obstruction, especially in the terminal or fourth portion, a duodenojejunostomy is indicated. If the duodenum is found to be freely movable, it should be fixed so as to approximate its normal curvatures.

Prognosis.—There is the same tendency in these cases of congenital defects with dilatation to recurrent attacks whether under medical or surgical treatment. If an organic obstruction has been relieved by operation, the result as a rule is good. The results obtained in the Vanderbilt Clinic—Presbyterian Hospital series are shown in Table 8

DIVERTICULUM OF THE DUODENUM

Definition.—A pouch or sac-like eversion of a part of the duodenal wall

Etiology.—Diverticula may be congenital or acquired. They probably begin as a congenital weakness and increase in length and diameter with continued or increased internal pressure.

Frequency.—It is extremely difficult to give accurate figures, inasmuch as those quoted vary with the interest of the roentgenologist in the subject and the character of the clinic in which the cases have been studied.

Fig 517

Fig 518

Fig 517—Congenital defect of the duodenum with the curve to the right of the third portion

Fig 518—Congenital defect of the duodenum with a deviation of the fourth portion to the right instead of to the left.

Treatment.—Surgical treatment should not be advised unless conservative measures, as outlined by Crump, have completely failed after prolonged trial or unless repeated barium studies definitely show an organic

Pathology.—In the majority of cases the circular and longitudinal coats of the duodenum are missing, and the mucosa and muscularis mucosae make up the wall of the diverticulum. Peritoneum is absent except in

those diverticula occurring in the anterior aspect of the first portion.

The majority of diverticula are found in the second, or descending portion and along the pancreatic or mesial aspect. They vary in size from one to several centimeters in length. If the neck is narrow and the diverticulum empties with difficulty, stasis of food results and inflammatory reactions of vary

periumbilical which is made worse rather than relieved by eating and in this way differs from ulcer pain. The diverticula that empty with difficulty either because of the dependent position or narrow neck usually cause more constant and severe symptoms.

Physical examination may or may not show a constant point of tenderness over the diverticulum.

TABLE 8—RESULTS OF TREATMENT OF CONGENITAL DEFECTS OF THE DUODENUM IN THE VANDERBILT CLINIC—PRESBYTERIAN HOSPITAL SERIES

	Cases	Cured	Improved	Failures	Not followed

Total	62	4	16	8	34

ing degree may be noted. Most of the diverticula show no pathology other than the abnormal sac like process and defective muscular layers.

Symptomatology—In the series of 57 cases (Table 8) from the Presbyterian Hospital 39 were casual findings in the course of a barium study of the gastrointestinal

Diagnosis—As in the majority of cases of duodenal lesion the barium meal with fluoroscopy is the most dependable and usually the only means of diagnosis. Fluoroscopy is much more reliable than roentgenographic study but both should be made. Films showing a barium retention of six hours and more prove that there is delayed

TABLE 9—ANALYSIS OF 57 CASES OF DUODENAL DIVERTICULA STUDIED AT THE PRESBYTERIAN HOSPITAL

Total	15	42	23	21	30	7	16	4	8	9	21	4	37	10	4

* The patients were operated on for lesions other than diverticulum.

tract for other lesions. 28 lesions other than diverticula were found by x-ray examination or at operation in this series. One may safely say that only about half of the diverticula cause symptoms. These are equally divided between those of digestive disturbances (such as belching and upper abdominal distress) and real pain epigastric or

emptying. X-ray studies differentiate this lesion from other duodenal, gastric and biliary tract disorders with which its symptoms are most often confused.

Treatment—If the diverticulum empties easily shows no six hour residue and is not tender on direct palpation then in all probability it is harmless and no therapy is

needed. If it returns barium is placed dependently and is tender to pressure an ambulatory ulcer diet and ulcer regime with or without gastric lavage should be given a thorough trial. If these measures fail and tenderness and signs of inflammation (a diverticulitis) persist surgical removal is indicated.

Prognosis—Of the 7 patients in this series operated on for diverticulum all were cured of their symptoms. Five of the diverticula were excised 2 were inverted into the duodenum and the base closed because it impinged on the papilla of Vater. Operation for removal of a diverticulum if any other pathologic condition is present will result in a continuance of symptoms.

ACUTE DUODENAL OBSTRUCTION

(*Acute Duodenal Ileus Acute Arterio-mesenteric Ileus Acute Gastromesenteric Ileus*)

Definition—An acute obstruction of the duodenal lumen as a result of pressure from outside or within the wall of the duodenum.

Etiology—The most common cause of acute duodenal obstruction is considered to be the angulation of the third or preapertic portion of the duodenum by the superior mesenteric vessels. Viscerptosis and atony of the duodenum are predisposing factors as is the flint dorsal or recumbent position. Hemorrhage into the wall of the duodenum into the pancreas or into the periduodenal tissues or edema of the pancreas may shut off the lumen of the duodenum. Resection of the duodenum with duodenorrhaphy may cause narrowing or angulation sufficient to result in acute obstruction.

Pathology—The duodenum is found to be acutely dilated with an associated acute dilatation of the stomach with an acute angulation at the point of the duodenum where the superior mesenteric vessels cross it. As the duodenum fills the angulation increases especially if the walls are atonic. There may be hemorrhages in the wall of the duodenum. If the hemorrhage is massive as in jaundice or when associated with pancreatitis the lumen of the duodenum may be obliterated.

The pancreatic secretions and bile of which each averages from 800 to 1000 cc in

twenty-four hours as well as the gastric secretions tend to cause rapid dilatation of the stomach and duodenum proximal to the obstruction.

Symptomatology—The patient presents all the symptoms and signs of a high intestinal obstruction: *i. e.*, great prostration restlessness rapid pulse repeated vomiting of large amounts of bile stained fluid with later fairly constant spilling over of the same material. This results in rapid dehydration and loss of sodium and chlorine radicals as shown by electrolytic studies of the blood leading to tetany decreased urinary output and death.

Physical Signs—Distention of the upper part of the abdomen with succussion sounds is characteristic. Gastric lavage reveals large amounts of gas and stomach and duodenal contents which may amount to from 2 to 4 liters. The patient appears restless pinched and dehydrated and has an increasingly rapid pulse.

Treatment—In the cases caused by angulation of the superior mesenteric vessel placing the patient in the head-down prone position and lavage with water at a temperature of 110° F. will usually produce prompt and curative results. Intravenous infusion of Ringer's or normal salt solution to combat base loss is essential. If the lumen of the duodenum is obstructed by pressure from without or by causes in the wall of the duodenum a gastroenterostomy may prove effective as a short-circuiting procedure.

Prognosis—Unless the angulation of obstruction is relieved within the first twenty-four hours the patient shows a rapid downhill course. It is extremely important to recognize the condition early and apply remedial measures promptly to prevent death.

CHRONIC DUODENAL STASIS

Synonyms—Chronic duodenal ileus chronic duodenal dilatation chronic duodenal obstruction chronic duodenal retention.

Definition—A constant or recurrent delay in the passage of duodenal contents with or without dilatation and with or without demonstrable mechanical obstruction.

Etiology—When chronic duodenal stasis is associated with mechanical obstruction the latter may be the result of congenital or

acquired bands or adhesions of pressure of the superior mesenteric vessels or of angulation associated with an anomaly of curvature or rotation of the duodenum. The obstruction may be caused by pressure from without or inside the wall of the duodenum by a tumor or inflammatory scar tissue.

Chronic duodenal stasis occurs without any demonstrable organic cause of obstruction. The reverse peristalsis and atony can be explained only on a neurogenic basis reflex or inhibitory impulses interfering with the normal physiologic movements of the duodenum. These cases are the most difficult to explain and the most unsatisfactory from the therapeutic standpoint.

Pathology.—In the cases associated with organic obstruction the pathology varies with the factors mentioned under etiology. The mere presence of veil-like adhesions does not constitute a mechanical obstruction but any of the following constitutes a valid pathologic condition: the definite angulation as a result of a band of fibrous tissue; congenital or inflammatory, a congenital anomaly of curvature or rotation or of pressure of superior mesenteric vessels; a cicatricial stenosis secondary to ulcer, or pressure from without or within the wall of the duodenum as a result of neoplasm.

In these cases as well as in those in which no organic obstruction is demonstrable there is a varying degree of dilatation. In the former, especially with a gradually increasing obstruction—as in stricture of a jejunal ulcer—the walls of the duodenum are hypertrophied.

Symptomatology.—In comparing the major symptoms of the patients with organic obstruction and those without real obstruction (Table 10), it will be seen that they are common to both conditions in two particulars; do they differ? In duodenal stasis due to real mechanical obstruction with gradual narrowing of the lumen the vomiting is more constant without periods of well-being. In duodenal stasis without demonstrable obstruction the vomiting pain or epigastric distress and other digestive disturbances come on in an attack associated with emotional disturbances or fatigue and followed by an interval of freedom from symptoms. In these cases it will be noted that the anxiety factor is demonstrated in a

far greater proportion. Furthermore there is a higher incidence of asthenic and stolic habitus in this group.

Physical signs are not at all characteristic except in the cases in which there is gradually increasing duodenal stenosis with a markedly dilated hypertrophied duodenum. Here right upper quadrant distention succussion and splashing can be made out.

Diagnosis.—The most reliable and the essential diagnostic measure is the barium meal with fluoroscopy. Roentgenograms may or may not show dilatation and will not show the reverse peristalsis revealed by fluoroscopy. An experienced roentgenologist can usually demonstrate real organic obstruction and predict the findings at operation. A study of these cases by internist roentgenologist and surgeon is essential if errors in diagnosis and therapy are to be avoided.

The lesions to be differentiated largely by roentgen study, are gastric and duodenal ulcer, gastric carcinoma, disease of the gall bladder, pancreatic inflammation, cysts and tumors.

In the cases in which organic obstruction due to ulcer stenosis of definite constant narrowing by congenital or acquired bands is demonstrated in the fluoroscopic studies medical therapy as outlined by Crump should first be tried. If there is an underlying anxiety factor, this should be dealt with by the physician experienced in psychoanalysis. After a thorough trial of conservative measures, especially if obstruction is shown to be increasing surgical treatment is indicated. A release of the obstruction or angulation by sectioning fibrous bands most commonly hepatoduodenal may be all that is required. If the obstruction can be demonstrated in the third or fourth terminal portions or if it is due to stenosis of the jejunum just distal to the duodenojejunal junction duodenojejunostomy is the correct operation. Gastroenterostomy is not as physiologic does not give as direct short circuiting and in the follow up studies shows unsatisfactory results.

Prognosis.—In these cases the prognosis depends on whether the duodenal stasis is caused by organic obstruction or is a functional affair. In the latter group psychotherapy is more important than all other

TABLE 10.—RECAP OF THE SYMPTOMS AND ROENTGEN FINDINGS IN CASES OF DUODENAL STASIS WITH AND WITHOUT DEMONSTRABLE OBSTRUCTION

	Number of patients	Average age, years	Males	Females	Range in chronicity of symptoms 3 wks to 25 yrs	Indigestion	Bloating and belching	Headaches and dizziness	Pain	Pain, epigastric	Pain in right upper quadrant	Periumbilical pain	Nausea	Vomiting	Constipation	"Nervousness"	Definite anxiety factor	Onset with infection	Loss of weight	Pleitic habitus	Obese habitus	Roentgenographic findings					
																						Duodenal delay	Duodenal dilatation	Hepatic dilatation	Duodenal mesenteric	Duodenal anomaly	Gastric residue
Chronic duodenal stasis with demonstrable obstruction	30	50	14	22	3 wks to 25 yrs	11	5	4	20	19	1	4	10	19	10	10	10	2	16	18	3	16	26	15	6	5	15
Chronic duodenal stasis with demonstrable obstruction	50	57	18	59	4 wks to 10 yrs	33	21	1	33	21	6	6	23	23	22	8	10	4	2	20	3	51	24	14	3	4	6

measures. The anxiety factor should be dealt with in the same way if it exists in the cases showing mechanical obstruction. Table II shows the results in therapy in the series from the Presbyterian Hospital. The author is convinced that many of the results hitherto published are too optimistic, because not based on careful or prolonged follow-up studies.

DUODENAL FISTULA

Varieties.—There are two varieties of duodenal fistula, the external and the internal.

Definition.—A duodenal fistula is a tract which communicates between the lumen of the duodenum and some other viscus or the

there is no obstruction to the normal lumen of either viscus which enters into the fistula.

Symptomatology.—Symptoms are usually absent. If the duodenum communicates with the colon, rapid loss of weight and strength will result. The patient will have diarrhea, and the stools will contain large amounts of bile. There may be fecal-smelling vomitus.

Diagnosis.—Except for the rare communication between the duodenum and another part of the intestinal tract, discovered by barium roentgenographic studies, these fistulas are undiagnosed unless the patient is operated on or comes to autopsy.

Treatment.—If x-ray studies show a communication between the duodenum and the

TABLE II.—*Summary of the Results Obtained in Cases of Chronic Duodenal Stasis*

														Section of band	Duodenojejunostomy	Gastroenterostomy	Duodenorrhaphy or duodeno-gastrostomy			
Chronic duodenal stasis with out demonstrable obstruction	26	4	0	3	1	7	13	2	1	6	4	0				5	4	0		
Chronic duodenal stasis with demonstrable obstruction	30	2	6	6	0	16	25	11	2	6	0	4	13	5	17	7	0	3		

outside surface of the body. The former is termed an internal and the latter an external duodenal fistula.

1. Internal Duodenal Fistula.—Etiology.—The most common cause is a gallstone ulcerating through the wall of the gallbladder and the adjacent adherent duodenum. An ulcerative process between the duodenum and some other part of the adjacent intestinal tract may result in an internal fistula.

Pathology.—If the internal fistula unites the duodenum with the gallbladder, it will remain open if bile continues to flow through the fistula owing to obstruction of the common duct below the cystic duct. The tendency is for an internal fistula to close if

colon or stomach, and especially if the patient has diarrhea and has rapidly lost weight and strength, an operation to close the fistula is definitely indicated. The other varieties, as a rule, give no symptoms. If disease of the gallbladder is present, surgical treatment may be necessary, and the duodenal opening can be attended to at the same time.

Prognosis.—The closure of an internal duodenal fistula is usually an easy procedure. The results are excellent in closure of a fistula between the duodenum and the gallbladder, this being done by removing the gallbladder and closing the opening into the duodenum. In duodenocolic fistula the patient is often greatly depleted, and the dan-

gers of an external colic or an external duodenal fistula following an attempt to close the internal fistula compromise the recovery.

2 External Duodenal Fistula—Etiology—The most common cause is disruption of the inversion of the duodenal stump following resection of the stomach for ulcer or cancer. Owing to the edema of the gastrojejunostomy or angulation of the stomach the contents of the duodenum—bile and pancreatic fluid—rapidly accumulate and burst the duodenal stump. Other causes are insecure closure of an incision into the duodenum for excision of ulcer, the inadvertent application of a clamp to the duodenal wall during a right nephrectomy, and insecure anastomosis of the duodenum to the common duct or gallbladder for the relief of obstruction of the common duct.

Pathology—Because of the digestive action of duodenal contents activated pancreatic ferments the walling-off process of the peritoneum is greatly compromised and subperitoneal and subcutaneous tissues and skin between the duodenum and body surface undergo digestion. Unless this action is checked by neutralizing the ferments or by sucking out the duodenal contents the area around the fistula enlarges and wide raw painful skin surfaces are exposed to the proteolytic pancreatic juice.

The loss of fluid and especially of base in the duodenal contents results in very rapid dehydration and changes in the electrolytes of the blood.

Symptomatology—There is no more serious complication in abdominal operations except for massive hemorrhage than an external duodenal fistula. It usually complicates a serious operation and develops as a rule within the first few critical days of convalescence. A copious bile stained fluid flowing from the operative incision or drainage tract is usually the first sign of the establishment of the fistula. The patient complains of thirst and rapidly becomes dehydrated. Fluids such as milk or thin gruel appear in the fistulous tract promptly after ingestion. The peripheral skin rapidly becomes irritated and painful and soon shows proteolytic digestion. As dehydration increases the urinary output decreases. Examination of the blood shows a decrease in chlorides and a change in the proportion of

the electrolytes of the blood is noted. Within twenty four hours the patient may become extremely weak and thirsty, has a rapid pulse and has a pinched look. Tetany may develop as a result of the loss of bases in the blood.

Treatment—It is essential to recognize this complication promptly. Three measures offer the most definite relief. 1 Sodium chloride should be supplied intravenously or subcutaneously in the form of sterile Ringer's solution or normal salt solution. A continuous intravenous drip to supply the patient with 3000 or 4000 cc of salt solution is the surest method. 2 A jejunostomy by means of a No. 18 or 20 F catheter should be made through which the patient can be given glucose solution and peptonized milk in 100 cc amounts every four hours. 3 The patient should have dressings removed and by means of a frame over the abdomen covered with a blanket or sheet continuous suction should be established to draw up the duodenal contents as they well into the fistulous opening. An electric light bulb kept a foot or so above the surface of the skin will provide warmth and keep the skin surface dry around the fistula. Thus avoid continuous painful changing of dressings and keep the patient warm and comfortable. Attempts to close the fistula especially if it is on the posterior surface are useless.

Prognosis—From 40 to 50 per cent of the patients die unless promptly and properly treated. The fistula closes within two or three weeks if the patient survives the first week.

DUODENITIS

Duodenitis is a lesion that is difficult to define. It has no known etiology. The pathology is not well understood and the symptoms are easily confused with those of duodenal ulcer, diverticulum and disease of the gallbladder. Both the treatment and the prognosis are as yet poorly defined and uncertain.

Within recent years some surgeons and roentgenologists have described a condition characterized by marked reduplication of the duodenal mucosal fold especially of the bulb and irritability and tenderness over the duodenum as seen in the barium meal examination and have called it duodenitis. The patient gives a history suggestive of a du-

duodenal ulcer or duodenal polyp. In many cases operation is performed with the diagnosis of duodenal or gastric polyp because of the redundant mucosa obstructing the pylorus. The treatment that is indicated when this condition is found at operation is a modified Finney pyloroplasty with excision of part of the pyloric ring.

In the few cases in which operation was performed in the Presbyterian Hospital an incorrect diagnosis of duodenal polyp was made.

FOREIGN BODY IN THE DUODENUM

Sharp objects like pins or needles or fish bones may become embedded in the duodenum and may necessitate removal. One of the patients at the Presbyterian Hospital was brought in as an emergency case from a nearby otolaryngologic hospital and had a radium tube in the lowermost portion of the duodenum. This of course required immediate operative removal.

The majority of patients can be watched safely for a few hours to note the progress of the object beyond the duodenum. As a rule the object even when sharp is passed per rectum. If by x-ray study it is seen to remain in a fixed position in the duodenum, operative removal is indicated.

TUMORS OF THE DUODENUM

Tumors of the duodenum are as rare as tumors of the stomach are common. In the Presbyterian Hospital series the author could find only 13 cases reported. Rufford, in reporting the cases of tumors of the small

and palliative gastroenterostomy for relief of duodenal obstruction is the only relief that surgery can offer. Carcinoma of the papilla of Vater is at times a debatable lesion; some pathologists considering that certain of these are of duodenal mucosal origin. These cases have not been included in this group as the great majority involve the common duct and pancreas before they do the duodenum.

Duodenal polyp gives the sentinel symptom of hemorrhage. Patients are given a barium meal to determine the source of hemorrhage, being considered as having an ulcer, and the diagnosis of polyp is made. The majority of these polyps occur in the first portion of the duodenum and may be so pedunculated as to pass through the pylorus. They may or may not be associated with pain. Polyps are easily removed through an opening in the duodenum and show no tendency to recur.

intestine from the Johns Hopkins Hospital series found 88, 21 of which were tumors of the duodenum. Table 12 shows the cases of tumors in the Presbyterian Hospital series. Fortunately, polyps are the most common and excision gives excellent results. Carcinoma and sarcoma are as a rule inoperable.

DUODENAL ULCER

Incidence—Since the beginning of the century when Moynihan first stressed its incidence duodenal ulcer has been recognized as a rather common cause of indigestion. Some authorities claim that about 1 in 10 of the adult population at some time suffers from a duodenal ulcer. The condition is much more common in males than in females; combined figures from several large clinics showing 79 per cent males. Duodenal ulcer may be found in patients of any age but it is most frequent in the third and fourth decades. Several cases of its occurrence in infancy and childhood are recorded in the literature. The question of influence of occupation on the incidence of duodenal ulcer is debatable but exacerbations do occur under conditions of nervous stress and increased activity. In this connection it is well known how frequently duodenal ulcer occurs in physicians who as a class are subjected to the nervous tension of assuming grave responsibilities. In a series of cases of duodenal ulcer occurring in the city of New York the occupation most frequently noted was that of taxi driver. It would be difficult to imagine a more trying stress and strain occupation than this when associated with the relentless competition that prevails in a large city.

Varieties—1. Acute duodenal ulcer which is limited to the mucous membrane occurs as a complication of some acute or chronic infection and its existence is likely to be overlooked except in the comparatively rare case in which the process progresses and hemorrhage or perforation occurs. Duodenal ulcer as a complication of superficial burns described in 1842 by Curling is present in a relatively small percentage of cases.

2. Chronic duodenal ulcer which penetrates deeper into or even through the wall and is associated with extensive reactive tissue changes is the common form encountered.

Etiology—The pathogenesis of peptic ulcer has been diligently and intelligently studied both clinically and experimentally by many able investigators. However as pointed out by Boyd the mere fact that an ulcer can be produced in the laboratory by some ingenious method need not necessarily

bear any relation to the causation of the common peptic ulcer of actual practice.

The hereditary factor at times is important. Alvarez in his splendid study of this problem of etiology describes as the ulcer type the keen alert sensitive man who is constantly driving himself (this description is substantiated by ample clinical proof).

It is evident that any nutritive injury to the duodenal mucosa from any cause whatever makes possible a digestion of tissue and thereby gives rise to ulcer. Erosion of the mucosa may follow irritation by means of chemical, physical or mechanical trauma. Bergsma reports a high incidence of ulcer in Abyssinia where the food is heavily peppered, and Sommerville and McCarrison have pointed out that in parts of southern India there is a frequency of ulcer supposedly due to a diet of tnpica.

Local and alimentary infections undoubtedly play an important part. Rosenow has produced duodenal ulceration by intravenous injections of large numbers of certain strains of streptococci. Eusterman has called attention to the flare-up in the symptoms of ulcer caused by the common cold and has pointed out that gastric hemorrhage often follows an attack of influenza or sinusitis.

Arterial changes are probably a factor. Reeves has called attention to the fact that anatomically the duodenal cap is poorly supplied with blood and he has demonstrated that the vessels of the first part of the duodenum are delicate and long with an arrangement that probably predisposes to thrombosis. The influence of vasomotor spasm in the production of relapses of duodenal ulcer has been emphasized by von Bergmann.

The experimental work of Mana and Williamson, Bruce, Morton, Matthews and Dragstedt has definitely shown that whatever may be the cause or causes of local necrosis the digestive action of the gastric juice is the important factor in the conversion of an area of necrosis into an actual ulcer. Ulceration of the duodenum and stomach has been produced experimentally in animals by Walpole and others. Histamine in beeswax was implanted in the muscles and the effects were attributed to the prolonged sustained secretion of an acid gastric juice.

The influence of the nervous system in the etiology of ulcer is no doubt vital especially with respect to the derangement of the normal protective mechanism against ulcer. The presence of an ulcer diathesis (Hurst) is generally recognized and the increase of motor and secretory activity of the stomach is characteristic of the person with duodenal ulcer. The predisposing factor establishing the so called duodenal stomach (Gray) is the relative increase in vagus excitation established by diminished sympathetic control or by increased vagus stimulation. Crile has called attention to the importance of nervous stimulation in these cases. Cushing calls attention to the part that the interbrain plays in connection with the parasympathetic system and emphasizes the relation between peptic ulcer and stimulation of the interbrain. Robertson and Hargis observed a common occurrence of ulcers in patients dying of exophthalmic goiter. Langley has shown that nicotine paralyzes the synapses of the sympathetic nervous system and the influence of excessive use of tobacco on patients with ulcer has been commented on by many observers.

While the initial production of duodenal ulcer may be understood the factor or factors in the persistence of the ulcer or its tendency to recurrence have not been adequately explained by either clinical or laboratory investigators. However with regard to the problem of recurrence it is advisable to study the anthropologic type of the patient in his reactions as well as the gastric juice and the manner in which it is secreted (Alvarez).

Ochsner, Gage and Hosoi in 1936 published an excellent review on the etiologic factors. They divide the causes into two groups: (1) predisposing factors which include tissue susceptibility and constitutional predisposition and (2) precipitating factors which consist of hypersecretion, hyperacidity, focal infection and gastric trauma.

Two factors emerge as having a major role in any consideration of the etiology of duodenal ulceration: the persistent hyperacidity and hypersecretion throughout the whole twenty-four hours and the exposure of the duodenal mucosa to a small stream of acid—the jet mechanism. This may have a bearing on the relative infrequency in wo-

men because they possess a flatter type of duodenum which allows more certain quick neutralization of the acid.

Pathology—Acute ulcers may be irregularly distributed in the duodenum and may be multiple. These have a natural tendency to heal rapidly although perforation or hemorrhage may occur.

Chronic duodenal ulcers are almost always situated in the suprapapillary region within 5 cm. of the pylorus where they are exposed to the action of the unneutralized acid gastric juice. They may arise on the anterior or posterior wall or on both walls. They are usually small and punctate and show little tendency to induration. Caloused duodenal ulcers are not uncommon however and if anterior they tend to become adherent to the liver but if posterior they tend to become adherent to the pancreas. M. J. Stewart reports that ulcers of the posterior wall are usually one and one-half times the size of those on the anterior wall. The ulcers are usually rounded or oval, irregularity in shape occurring at times in the smaller ones. The characteristics of the crater margin, floor and walls as well as the serosal aspects depend on whether the ulcer is active, indolent or healing. The chronic indolent ulcer may have thickened undermined edges, an indurated floor and a sloping wall while the more acute form may have a punched-out appearance with soft congested walls and floor. The serosa in chronic ulcer is usually thickened and whitish stippling may be observed.

In the pathologic course of a chronic duodenal ulcer the following may occur:

1. **Healing**—This may occur without further serious change leaving a smooth scar.
2. **Perforation**—This may be acute especially if the ulcer is situated on the anterior wall. Chronic perforation of the posterior wall with involvement of the pancreas is not uncommon.

3. **Erosion of blood vessels**—The superior pancreaticoduodenal and the gastroduodenal arteries may be involved in ulcers of the posterior wall causing hemorrhage.

4. **Cicatrization with stenosis**—Duodenal occlusion may occur with dilatation of the stomach. Stenosis of the ampulla of Vater with obstruction of the outflow of bile and pancreatic juice has been reported.

5 Periduodenal adhesions Periduodenitis with adhesions to surrounding structures and viscera is common Occasionally diverticula of the duodenum may follow cicatrization of an ulcer

6 Malignant change This is extremely rare in cases of duodenal ulcer although some cases have been reported

Statistics do not agree as to the frequency with which ulcer of the duodenum is accompanied by gastric ulcer M J Stewart in 4000 consecutive autopsies including 153 cases of active duodenal ulcer and 89 cases of gastric ulcer found only 2.6 per cent of the chronic duodenal lesions to be accompanied by chronic lesions in the stomach Wilkie in a series of 300 patients with ulcer on whom he operated found coincident gastric and duodenal ulcers in 40 cases (14 per cent) Walters in a study of the antrums of stomachs removed at the Mayo Clinic by partial gastric resection for duodenal ulcer found a very infrequent association of gastritis

Symptoms—An acute ulcer of the duodenum usually does not give rise to symptoms unless perforation or hemorrhage occurs It is usually so superficial that no local or distant reflexes are excited by irritation and the inflammatory reaction is scant

The history of *chronic duodenal ulcer* is usually a long one in which there have been remissions often with complete relief from symptoms Periodicity may be marked and the attacks appear to be more frequent in autumn and spring Nervous and physical fatigue or an infection of the respiratory tract may initiate an attack but probably the most common of all exciting causes is dietary indiscretion Excessive use of alcohol or tobacco is also an important factor

The most constant and distinctive feature of ulcer is pain Its character varies It may be burning boring aching or gnawing in some cases it amounts to no more than a vague sense of pressure in the abdomen Moynihan described it as hunger pain since it is felt particularly when the stomach is empty coming on from one to six hours after a meal the interval often being in direct ratio to the size of the meal and being relieved by ingestion of food or alkali or by self induced vomiting It is not unusual for the patient to be awakened by pain in the

early morning hours Pain coming on in the night suggests obstruction Pain is usually felt in the midline or just to the right often being localized midway between the xiphoid and the umbilicus although it may radiate to the back or sides Radiation of pain is frequent in cases of penetrating or stenosing ulcer Wilkie stated that an atypical history without hunger pain is more common in women than in men being present in 30 per cent of 94 cases of duodenal ulcer in females studied by him Nausea and vomiting are infrequent in uncomplicated cases but the regurgitation of sour liquid is not uncommon Relief obtained from vomiting may cause the act to be repeated so often that the patient may regard it as a symptom

In the absence of definite hemorrhage anemia does not usually develop although the presence of occult blood in the stools may be constant occasionally slight persistent oozing may cause secondary anemia About 25 per cent of patients with duodenal ulcer have bleeding as evidenced by hazy stools or the presence of occult blood Disordered bowel function and loss of weight are not marked in uncomplicated cases although there may be constipation Latency in production of symptoms is not rare in cases of duodenal ulcer and severe hemorrhage or acute perforation may be the first symptom noted

Physical Signs—The uncomplicated duodenal ulcer is characterized by a lack of physical signs The chief value of physical signs in duodenal ulcer is in the exclusion of conditions simulating ulcer and in the disclosure of possible foci of infection Localized tenderness in the central or right lateral portion of the upper part of the abdomen may be present If marked it suggests that the ulcer is inflamed adherent or penetrating Rigidity of the upper right rectus muscle may be observed owing to exaggeration of the upper abdominal reflex but it is by no means a constant finding In the presence of complications the physical signs are usually quite characteristic of the existing condition

Special Examinations.—*Gastric Analysis*—The fractional test meal usually shows a tendency to hyperchlorhydria or high normal acidity curves in uncomplicated cases of chronic duodenal ulcer In some cases there is evidence of normal or rapid

emptying of the stomach with continuous after-secretion. The specimens may contain chemical or microscopic evidence of blood.

Röntgenologic Studies.—If properly performed and correctly interpreted, these will reveal the presence of an ulcer in a very large percentage of cases. A fluoroscopic examination should always be made. A niche in the duodenal bulb caused by the crater of an ulcer or deformity of the duodenal contour due to cicatricial contraction, with evidence of a combination of retention and hyperperistalsis in an otherwise normal stomach, is the usual finding. The rugae may assume a star-like pattern, owing to the scar tissue contracture in the region of the ulceration.

simulated by those of other lesions, and the laboratory and roentgenologic studies may be confusing. A complete and comprehensive history, especially with respect to discomfort or pain; careful clinical observation; a thorough physical examination, to rule out conditions which may mimic ulcer; a careful laboratory study, especially the fractional test meal, and a competent roentgenologic examination will in most cases establish a correct diagnosis. The differential diagnosis between duodenal ulcer and functional nervous gastric disorders is frequently difficult. Symptoms identical with those produced by an active ulcer may be complained of by the patient possessing a gastric and nervous

Fig 519—A, Normal duodenal bulb. Contraction wave in the stomach approaching the pylorus. The pyloric sulcus indicates the division between the stomach and the duodenum. The normal bulb resembles an ace of spades. B, An unusually clear demonstration of a duodenal ulcer. Ulcer of the lesser curvature side of the duodenal bulb with an annular indurated area surrounding the ulcer crater. Opposite the ulcer crater on the greater curvature side is a spastic indrawing of the wall of the duodenum. (Courtesy of Dr. Earl R. Crowder.)

Vaughan and Singer have pointed out the value of roentgenograms in the diagnosis of perforated peptic ulcer through detection of spontaneous pneumoperitoneum. Ulcers on the posterior duodenal wall are especially difficult to visualize. Their presence may sometimes be determined by the spot of barium left in the crater after the main part of the barium meal has passed on.

Stool Examination.—After a meat-free diet for forty-eight hours the stool should be examined in all cases to detect the presence or absence of fresh or occult blood.

Diagnosis.—The problem of arriving at a correct diagnosis of duodenal ulcer is frequently perplexing. The symptoms are often

constitution which predisposes to the development of ulcers. A roentgenologically normal duodenal bulb and persistent absence of occult blood in the stools establish a correct diagnosis in most instances. A routine neurologic examination must be carried out with great care for those patients in whom gastric crises of tabes must be considered.

Chronic appendicitis and cholecystitis, especially in the mild form, may give rise to reflex dyspepsia, with pain closely simulating that of ulcer. Less commonly, reflex gastric symptoms may be present in cases of organic lesions or adhesions of the colon, esophagus, prolapsed kidney, small epigastric hernia, pancreatic disease and intestinal

tuberculosis. The irregularity of the pain in its time of onset, intensity and mode of relief as well as the presence of positive physical signs indicative of the local condition are significant factors in arriving at a correct diagnosis. The not infrequent association of chronic cholecystitis and chronic appendicitis with duodenal ulcer (chronic) must not be forgotten.

In cases of chronic duodenitis, chronic gastritis or both unassociated with actual duodenal ulceration but with symptoms suggestive of ulcer, careful and repeated roentgen examinations and gastric analysis are important factors in the differential diagnosis. The coexistence of these lesions with duodenal ulcer has been reported as occurring with varying percentages at different surgical clinics.

Mathieu in a study of 664 cases of carcinoma of the stomach found that in 8 per cent the symptoms quite closely simulated the typical symptoms of duodenal ulcer. He pointed out that the chief features that distinguish them from the symptoms of duodenal ulcer are the absence of spontaneous remissions and the severity of the pain from the onset.

Prognosis.—The tendency to long duration of the condition and the ever present possibility of the development of dangerous complications, especially perforation, must be appreciated in attempting a prognosis in cases of duodenal ulcer. While in general the prognosis is good, the possibility of securing a permanent cure by a single course of medical treatment or a single surgical procedure is frequently quite uncertain. A reliable prognosis can be made only through an intelligent evaluation of the patient's nervous and mental make up, his habits and environment, his ability to cooperate, the type of treatment applicable to his condition, the stage of the disease in which treatment is instituted and the presence or absence of associated disease or complications.

Complications.—Duodenal ulcer may be complicated by hemorrhage, perforation or obstruction. Infrequently gastric tetanus and occlusion of the common or of the procerate ducts may occur. Malignant growths of the duodenum are so rare that for all practical purposes they can be dismissed.

Hemorrhage.—The first indication of the

presence of a duodenal ulcer may be hemorrhage as evidenced by melena or hematemesis or both.

From hemorrhage of any moment some degree of faintness develops. Prompt recovery is the rule, however, and usually no further signs are present until the appearance of a tarry stool twenty-four hours later. Seldom does a single hemorrhage drive a patient to bed. Marked pallor, great thirst, restlessness, recurrent syncopeal attacks, a rapid small pulse, sighing respirations, a fall in blood pressure and tarry stools indicate a massive hemorrhage. Usually several days elapse before the full extent of exsanguination is evidenced by examination of the blood, because capillary contraction keeps the blood concentrated. Frequent blood pressure readings probably constitute the best clinical indication of the intensity of hemorrhage. Sometimes the patient is found collapsed on the floor in a dead faint. When a patient is admitted because of hemorrhage from the upper portion of the gastrointestinal tract, the immediate question confronting the attending physician is regarding the source of the bleeding. Sometimes it is possible to obtain a history that indicates that a duodenal ulcer is the source. At other times the differential diagnosis is extremely difficult. Bleeding may be coming from esophageal varices or from gastric lesions due to gastritis, ulcer, benign or malignant neoplasms. In any case the patient is put to bed and attempts are made to keep him at complete rest. This means the judicious use of morphine to allay fear, reassurance of the patient and treatment for shock if necessary. The duodenum should be put at rest also by withholding fluid and food by mouth so that a clot may form and occlude the bleeding point. Fluids may be administered subcutaneously or by proctoclysis. Intravenous medication is to be avoided as it may raise the pressure sufficiently to dislodge a newly formed clot. Small transfusions of 50 to 75 cc of blood may be used when anemia has reached an alarming level. This is more for the clotting effect than for the restoration of the blood volume. If the patient is young, bleeding usually ceases after a few days. When blood is no longer demonstrable in the stools, it is safe to resume feeding, carefully working up from fluids to a smooth

diet Recovery as a rule is rapid Rarely does the patient especially a young adult with chronic ulcer succumb to a first hemorrhage

The accumulation of blood in the colon and the distal portion of the ileum may cause toxemia due to all unimpaired digestion The temperature is elevated the pulse rate remains rapid and there is no desire for food Panchet suggests flushing the colon with a 2 per cent solution of sulfate of soda through a cecostomy It is quite apparent that rectal irrigation will not completely empty the proximal and midportion of the colon At autopsy the colon and the distal portion of the ileum may be filled with old blood, when it was evident clinically that death was not due to exsanguination

The source of blood in cases of chronic ulcer is generally an erosion of a small artery, and profuse hemorrhage rarely occurs from a chronic ulcer situated anywhere except in the posterior wall

Allen and Benedict in a study of 1804 patients with duodenal ulcer treated in the wards of the Massachusetts General Hospital found that 628 or approximately one third had gross bleeding Of these 40 per cent had minor bleeding without secondary anemia and 91.9 per cent bled severely enough to produce marked secondary anemia In this series over 5 per cent of all patients with gross bleeding eventually died of hemorrhage The mortality from sudden massive hemorrhage was 14.5 per cent, regardless of the treatment The most striking factor in determining the possibility of spontaneous recovery from hemorrhage in these cases was the age of the patient and these investigators concluded that spontaneous recovery is less likely with increasing age as death rarely occurred from hemorrhage in patients under fifty

There has been a tendency in some clinics recently to treat massive gastric hemorrhage without restriction of diet The patient is given pureed food on a five meal daily schedule He is allowed as much food as he desires In addition alkalis atropine and iron are given The patient may move about in bed freely Meulengracht claims a greatly decreased mortality under this management This treatment may have sufficient merit to warrant a more widespread application

Balfour voiced what is probably the opin-

ion of most surgeons regarding immediate surgical treatment when he stated that the danger of succumbing to hemorrhage is less than the danger of operation during hemorrhage But it is a fact as stated by Allen that a small percentage of patients die from hemorrhage especially those who are older Consequently, it behooves the attending physician to keep this in mind and to be on the alert to detect the occasional case which will require surgical intervention as a life-saving measure even though the risk is great Gordon Taylor presents an excellent résumé on this difficult decision He declares that a policy of armed expectancy should be adopted even for a first hemorrhage as a large proportion of the fatalities are in this group Forty per cent of these deaths occur within the first three days

Hurst believes that the only indication for operation in the acute stage is the persistence of recurrence of severe hemorrhage while the patient is still fasting especially in individuals past middle life with a long history pointing to the presence of a chronic ulcer with arteries so degenerated that they are unlikely to contract sufficiently for satisfactory plugging by thrombosis

When the patient has recovered from the first hemorrhagic episode an attempt to demonstrate the ulcer by roentgen study should be made This may be safely carried out three weeks after cessation of hemorrhage In the event of a second hemorrhage from such a lesion operation should be urged after the patient has recovered and is in good condition This attitude is a safer one to assume than the risk of a succeeding serious hemorrhage The bleeding duodenal ulcer is usually on the posterior wall directly over a large vessel The erosion is often into the side of the vessel thus preventing it from retracting and stopping the hemorrhage In the older group of patients the lack of elasticity in the vessels is probably of moment

If surgical treatment is indicated the operation of election is exposure of the bleeding ulcer the cutting off of its blood supply by overlapping sutures about it or excision of the ulcer if feasible and in some instances at the discretion of the surgeon the performance of gastroenterostomy preferably posterior, if the condition of the patient was

rants it. In some instances a Finney-Haberer anastomosis is most successful.

Perforation—Perforations may be acute, subacute or chronic. The acute perforations may be further subdivided into gross and minute pinhole perforations.

Acute perforation may occur at any time and at any age but is most common between the ages of twenty-five and fifty. It is located on the anterior wall of the duodenum in most instances. It may follow the ingestion of a heavy meal or may occur during fasting. It has resulted from the manipulation of a barium meal in such instances perforation being apparent on the fluoroscopic screen. It may come on during exertion or it may happen while the patient is resting quietly in bed. When it follows exertion the patient often falls to the ground and cannot move without assistance. Perforation is initiated by sudden and severe localized epigastric pain which soon spreads over the entire abdomen and occasionally radiates to the chest back or shoulders. There is marked pallor, the face is drawn, the skin is cold, the temperature is subnormal, respirations are shallow and the abdomen is retracted, soon manifesting board-like rigidity. Tenderness in the epigastrium is present immediately over the right side, tending to become generalized but remaining most marked over the epigastrium. The peritoneal insult is severe. The pulse rate may be but little elevated and often remains normal. From two to four hours after perforation the patient usually shows evidence of reaction from shock. Vomiting may occur and if it is repeated several times the vomitus may be streaked with blood. Much does frank hemorrhage occur with perforation. The temperature rises to normal, the pain is less marked, the facies suggests less distress, the color improves and the pulse becomes stronger. If the patient is seen at that time the diagnosis may be difficult, particularly if the typical history of ulcer is lacking. This period may be regarded as a delusive calm and it is at this time that the patient frequently is first seen by the physician and the diagnosis may not be made.

Biliary renal or lead colic, acute hemorrhagic pancreatitis, mesenteric embolism or thrombosis, diaphragmatic pleurisy and ruptured ectopic gestation may present symp-

toms suggestive of acute perforated ulcer but the presence of associated signs characteristic of these conditions plus a carefully taken history usually establishes the diagnosis. Only the past history may suggest the correct diagnosis in cases of acute perforation of the gallbladder and of gangrenous cholecystitis.

The correct recognition of an acute abdominal emergency in which immediate operative treatment is required is the important point; the exact cause will be revealed at operation.

The symptoms of primary shock may set off in a few minutes or may persist for a few hours rarely longer. The patient improves generally, vomiting may cease and the abdominal signs may change but as a rule the tenderness and the rigidity persist with the same intensity. The dullness of the liver may be obliterated and roentgen examination may reveal pneumoperitoneum at that time. With abatement of intensity of the abdominal signs the diagnosis may prove to be quite confusing to one seeing the patient for the first time during the stage of reaction. The past and immediate history is important.

Twelve hours after perforation the patient's condition will again change with the advent of beginning peritonitis. Pain is more generalized and may be less severe, tenderness may be localized in the lower portion of the abdomen and the abdomen may show slight distention and may be softer. A mistaken diagnosis of appendicitis may be made at that stage.

The patient usually presents the typical picture of well-established peritonitis within twenty-four hours after perforation. Vomiting due to developing paralytic ileus usually is present. As a rule death occurs within from two to four days if an operation is not performed.

The pin-hole perforations are most difficult to evaluate. Many times the diagnosis is not made until operation has been carried out. The conditions confused with this are acute appendicitis, acute cholecystitis, pancreatitis, gastric crises of tabes and coronary occlusion.

The treatment of acute perforation is operative once the primary shock has been combated. Operation within from four to six

hours of actual perforation offers the best prognosis. The duodenum is exposed and the perforation is closed and reinforced with a tag of omental or mesenteric fat if possible. The presence of food and gastric secretion in the peritoneal cavity may be ignored. But if it is possible to suck out this material it will not serve as a foreign body focus for subsequent infection. The prognosis for recovery depends on the time which has elapsed since perforation. Within the first twelve hours it is usually favorable as lateral contamination of the peritoneum is rare until after this time. The surgeon should do as little as is consistent with the case in hand. This usually means simple closure of the perforation. More extensive operative treatment is contraindicated for several reasons. The terrain is most unfavorable for a complicated procedure. Complete disappearance of the ulcer follows in a fair number of cases. Complete relief of symptoms is obtained in 60 to 65 per cent according to White. In an additional 25 per cent of cases the patient will be comfortable on a medical regimen. In other words only 10 to 15 per cent of those who have had a perforated ulcer will ever require additional surgical treatment. It follows that it is poor judgment to put an already jeopardized patient through the unnecessary risk of a radical operation.

Drainage is not necessary within the first twelve hours as the peritoneum will usually take care of any infection that is present. In the late cases sulfa drugs should be used and drainage of the lateral gutters should be reserved until an abscess is definitely diagnosed.

Generalized peritonitis and pulmonary complications are the major factors in the postoperative mortality.

In cases of subacute perforation the resulting peritonitis is strictly localized as a result of plugging of the perforation by a tag of omentum or protective fibrin. The symptoms are similar to those of acute perforation but less severe and are not followed by those of developing generalized peritonitis. The rigidity and tenderness of the abdomen are most marked in the vicinity of the duodenum and later become confined to a small area.

Spontaneous cure usually follows this

form of perforation but a localized abscess may form and rarely does generalized peritonitis result.

Treatment of Subacute Perforation—Rest and starvation often result in complete cure of the ulcer. If an abscess is forming surgical drainage should be deferred until it is well localized. Laparotomy should be performed only if the symptoms and signs indicate a tendency toward development of generalized peritonitis.

Chronic perforation of an ulcer of the posterior wall is common and is due to a slow penetrating process resulting usually in involvement of the pancreas. This gives rise to no unusual symptoms and the treatment is essentially the treatment of uncomplicated chronic duodenal ulcer.

The development of a duodenoenteric or duodenojejunal fistula after perforation of an ulcer is extremely rare.

Obstruction in the duodenal bulb may be due to edema and congestion surrounding an active ulcer or to cicatricial stenosis. It is impossible clinically to distinguish obstruction due to spasm of the pyloric sphincter from obstruction due to edema or stenosis of the duodenal bulb.

Pain which is prolonged and especially marked at night and the vomiting of considerable food or excess gastric secretion at the end of the day are suggestive of obstruction. Hyperperistaltic action of the stomach occurs at first and may be distinctly felt by the patient or may even be visible. Later gastric atony develops and the stomach becomes a relaxed distended reservoir of food with vomiting of food taken a day or more earlier. Progressive starvation and dehydration combined will result in extreme emaciation.

Characteristic symptoms and signs plus roentgenographic and gastric test meal studies easily establish the diagnosis of duodenal obstruction.

In the treatment of patients with obstruction the condition should be carefully studied and a trial of medical treatment given before operation is advised. Subsidence of edema in a patient with an active ulcer or relaxation of a spastic pyloric sphincter will often relieve the symptoms of obstruction.

If relief is not afforded by a careful medical regimen then operative treatment may be

contemplated Preliminary medical treatment will tend to prepare the patient for operation. A gastrojejunostomy is often the operation offering the best results.

Tetany may result because of alkali in cases of obstruction and every means should be taken to combat the acid base unbalance before operation is attempted.

Occlusion of the bile or pancreatic duct may in rare instances develop as a result of extension of the inflammatory process or periduodenal adhesions. The surgical treatment depends on the coexisting lesions.

Malignant change in a duodenal ulcer is extremely rare but cases have been reported in the literature. If this condition is suspected partial gastric and duodenal resection should be performed in an attempt to control it.

Treatment—The treatment of complications having been discussed previously the treatment of a duodenal ulcer uncomplicated by hemorrhage perforation or obstruction will be considered here.

An acute ulcer if it manifests itself other than by acute perforation or hemorrhage should be subjected to medical treatment to which it will in most instances respond.

Successful treatment of the chronic and the recurrent duodenal ulcer is often a perplexing problem. In a consideration of the treatment of duodenal ulcer there are three salient facts that extensive clinical investigation has shown are well to bear in mind. The first of these is that the tendency to chronicity of a duodenal ulcer warrants the trial of a thorough detailed medical regimen in the average uncomplicated case before operation is undertaken.

The second fact is that the tendency of the well regulated course of medical treatment to subdue attacks and remove symptoms can lead the average patient to abandon irksome precautions in the false belief that he has been cured. Many patients suffering from duodenal ulcer have neither the determination and patience nor the time inclination and means to follow out indefinitely the exacting routine of medical treatment.

The third and perhaps most important fact is that a certain surgical procedure which in one clinic will give brilliant results when employed for a certain type of ulcer will in another clinic when performed in

exact detail on the identical type of lesion give poor results. There are probably three reasons for this. In the first place it is well recognized that the tendency to recurrence is greater in the mentally alert, highly nervous physically active person especially if he is Jewish than it is in the more phlegmatic and unemotional person. In the second place it has been shown by Walters of the Mayo Clinic that duodenal ulcer and its associated lesions especially gastritis differ in proportion among different people and in different countries. Finally, a certain percentage of recurrences may be due to failure on the part of the surgeon to realize the importance of first eradicating all the accessible foci of infection and then impressing forcefully on the patient the vital importance of adhering strictly to the postoperative treatment, especially with respect to securing adequate mental and physical rest to avoid ing dietary indiscretions—such as overeating and alcoholic indulgence and to the avoidance of an excessive use of tobacco.

Medical Treatment—The physician assumes a definite responsibility in caring for these patients as the complications carry a decided threat. There is a medical mortality which must be considered in the final analysis. The etiology being unknown the treatment both medical and surgical must rest on accumulated experience. Once the diagnosis has been established medical treatment should first be instituted.

The principles of medical treatment are the eradication of foci of infection the securing of mental and physical relaxation the establishment of gastric and duodenal rest and the neutralization of acidity. This may be secured by rest in bed with freedom from worry and lessening of nervous tension through use of sedatives. During early treatment feedings in small amounts may be given hourly, and later the administration of small frequent meals may be instituted. The basis of the diet should be cream milk eggs and cereal gruels. Medication as well as the diet is planned to keep the stomach free from acidity during a twelve-hour feeding period after which the stomach rests empty. Magnesium oxide or calcium carbonate depending on the degree of constipation present may be given alternately with small frequent meals. Olive oil is sometimes indicated

The activity of the ulcer is checked both clinically and by roentgenograms from time to time. When the patient resumes his usual life the eating of frequent small meals is essential and the prohibition of tobacco and alcohol is important. It is well to remember that during medical treatment complications may occur and that even when symptoms, signs and roentgenologic studies indicate a cure recurrence may follow.

Surgical Treatment—The surgical treatment for duodenal ulcer may be classed as follows:

- 1 Imperative—life saving
 - a Perforation
 - b Severe continuing hemorrhage

Fig. 550—Diagrammatic sketches of various gastric operations: A Anterior gastroenterostomy; B posterior gastroenterostomy; C Billroth's resection No. I; D Billroth's resection No. II; E Polya anastomosis; F Balfour anastomosis; G Moynihan anastomosis; H Devine oblique partial gastric excision.

- 2 Urgent
 - a Obstruction
 - b Repeated hemorrhages
- 3 Advisable—comfort bringing
 - a Persistent pain (local peritonitis adhesions to other organs)
 - b Unrelieved pyloric spasm
 - c Repeated failure of medical treatment
 - d When secondary to other foci (gallbladder appendix etc)
- 4 Recommended
 - a Unwillingness or inability of patients to carry out necessary medical regime

The object of any form of surgical treatment is to seek to relieve pain to limit trauma (passage of rough food) to secure better drainage to put the affected part at rest and to eliminate possible foci of infection elsewhere which may have a bearing.

The surgeon should never begin the operation with a preconceived idea as to what he will do. He should be prepared to do any one of a dozen different operations which may best suit the individual case at hand.

There has been a tendency in recent years toward a more extensive type of operation for duodenal ulcer. Massive resections of the stomach to reduce the acidity and the hypersecretion have been recommended by Con-

nell, Zollinger and Wangensteen. This is a swing to the therapy advocated years ago by European clinics and a minority group of American surgeons. Friedell and his colleagues have shown that a permanent reduction of the free hydrochloric acid in fasting contents followed in 75 per cent of the cases in which half or more of the stomach had been removed including the pylorus and antrum. If it is admitted that continuous acid secretion removes the defensive neutralizing mechanism the operation seems logical.

Diagrammatic representations of various technical procedures which can be employed

are given in figure 550. In recent years there has been a trend away from the operation of posterior gastroenterostomy. This has been due in part to recurring troubles which have arisen ten to twenty years after the operation. Nevertheless there are occasions when this operation is the most simple and most effective one available. If the ulceration is acutely inflammatory and adherent so that mobilization is dangerous this simple by-passing type of operation is effective. It is also excellent when there is obstruction. A more direct attack on the ulcer has been advocated by some surgeons. Local excision with various types of pyloroplasty while seemingly resting on good physiologic principles has not been successful as a form of therapy. The tendency to radical partial gastrectomy for simple duodenal ulceration has had a recent vogue. It is now the operation of choice for duodenal ulceration when operation is indicated. The results to date seem to show that the mortality is no higher in good hands. The patients have been able to be less cautious as to diet, with little evidence of upset. At the present time there is no ideal operation for duodenal ulcer resection of the stomach being a formidable procedure at best.

After the operation the patient should eliminate from his life those factors which may bring about a recurrent ulcer or the reactivity of an old one. If the postoperative principles of adequate mental and physical rest, small frequent meals, avoidance of the use of alcohol and tobacco and adherence to a sensible diet are not followed recurrence may appear in spite of the type of operative procedure performed. Occasionally also in spite of an intelligent choice of operative procedure and strict postoperative precautions the ulcer may recur.

In estimating the end results of any treatment it is well to remember the natural history of duodenal ulcer. This condition is subject to fluctuation in symptoms. There may be periods of complete remission. It is also well to bear in mind that a patient who has had one ulcer is always a possible candidate for another.

XXVIII THE SMALL AND LARGE INTESTINE

ANOMALIES OF THE SMALL INTESTINE

ATRESIA AND STENOSIS OF THE INTESTINE

Definition Etiology and Pathology —

Atresia of the intestine is a complete lack of intestinal continuity stenosis is a narrowing of the intestine Congenital atresia and stenosis of the small intestine are the result

ment during the solid stage (Fig 551) The cause of such arrests in development is still a matter of surmise Stenosis of the intestine represents an arrest of growth in a slightly later stage of development namely the stage of vacuolization and is manifested by a septum across the bowel with a small perforation in it (Fig 552) Such atresias and stenosis may occur at any point in the small intestine but are most commonly found in

Fig 551—The septum across the duodenum *a* The result of the arrest of development at the solid stage, *b* duodenojejunosomy for relief of the duodenal obstruction caused by *a**

of an arrest in the development of the embryo at an early stage Prior to the fifth week of fetal life the intestine has acquired a lumen lined with epithelium Between the fifth and twelfth weeks the intestinal lumen becomes obliterated by epithelial confluence and changed into a solid cord By the twelfth week the solid cord has become vacuolized the vacuoles have coalesced and the intestinal lumen has become reestablished Atresia is the result of an arrest in develop-

ment of the ileum next in the duodenum and next in the jejunum fortunately they are seldom multiple The bowel above the obstruction becomes dilated and that below remains collapsed In the patient with atresia the bowel below the obstruction appears like a small hard cord though on examination it is found to contain all the normal elements including a lumen This lumen however may be only large enough to admit a

* Ladd JAMA 107

small probe. In cases of stenosis the bowel below the point of obstruction is not as small as in the cases of atresia.

Symptomatology.—In the newborn infant the symptoms of atresia and stenosis are pain, restlessness, vomiting and lack of passage of normal meconium. On examination abdominal distention, visible peristalsis or coils of intestine and evidence of shock and dehydration are apparent. Exceptions to these usual findings may be noted in instances in which the obstruction is in the duodenum. In such cases the vomiting may

Fig. 50.—Roentgenogram of a patient with atresia of the duodenum which shows clearly the point of obstruction without the administration of barium.*

be sufficiently effective so that the stomach and duodenum are thoroughly emptied and consequently no abdominal distention or peristalsis is seen. A roentgenogram taken without the administration of barium is of value in confirming the diagnosis. The point of obstruction may be clearly outlined by the air in the dilated loop of intestine above it. The administration of barium in a suspected case of atresia is contraindicated as it will block the small lumen of the intestine below the obstruction after an anastomosis has been performed and thus prevent recovery.

* Ladd J.A.M.A., 101

ery. Another aid in confirming the diagnosis is the failure to find any keratinized cells in the stools (Farber).

Treatment.—When the diagnosis of congenital obstruction has been made the patient is prepared for operation by the parenteral administration of fluids to counteract dehydration and ketosis. For patients with duodenal obstruction a duodenojejunostomy is the operation of choice. A gastroyejunostomy may be performed in case the duodenal anastomosis is technically too difficult but the gastric operation is not so satisfactory. In patients with atresia lower down in the small intestine a lateral anastomosis should be performed by the special technique recommended by Ladd or that recommended by Webb and Wingensteen. The after-care is important and consists in maintaining the fluid requirements of the infant by administering glucose and saline solution parenterally, giving water and breast milk by mouth and aiding the dilation of the contracted bowel by means of saline enemas.

Prognosis.—Frazer in his book *Surgery of Childhood* states: "The prospect of recovery is exceedingly small. With improved technique and particularly with improved preoperative and postoperative care in well equipped children's hospitals the prognosis is much more favorable than it was a few years ago. In the Children's Hospital in Boston 99 patients with atresia and stenosis of the small intestine have been operated on with 29 recoveries."

MALROTATION AND NON-ROTATION OF THE INTESTINE

Incomplete rotation, malrotation and non-rotation are terms used to describe various abnormal abdominal conditions which are the result of arrest in fetal development during or after the return of the mid gut from the umbilical cord to the abdominal cavity. For an understanding of the conditions and for their successful treatment it is necessary to review some of the embryologic events which take place between the fifth and tenth weeks of fetal life. At approximately the fifth week of fetal life the abdominal viscera grow much more rapidly than the abdominal cavity with the result that there is insufficient room within the cavity to accommo-

date the organs which are destined to be located there. Nature meets this situation by temporarily transferring the mid gut: *e* that portion of the intestine supplied by the superior mesenteric artery into the base of the umbilical cord. In other words a temporary normal omphalocele occurs which lasts from the fifth to the twelfth week of fetal life. During this period the rate of growth of the abdominal cavity is accelerated so that by the tenth week it has acquired sufficient size to reaccommodate its organs. The return of the mid gut to the abdomen takes place in a particular way. The prearterial segment or that portion of the intestine extending from the duodenum to the vitelline duct returns first and passes from right to left behind the artery. The postarterial segment or that portion of the mid gut from the vitelline duct to the middle of the transverse colon returns next and passes from left to right in front of the superior mesenteric artery. The next stage of development consists in the descent of the cecum to the right lower quadrant and the fusion of the visceral and parietal peritoneum to give the mesentery of the small intestine its oblique attachment to the posterior abdominal wall and the cecum and ascending colon their stabilizing attachment to the right side. An arrest in development may take place at almost any stage of this process (Fig 553). Thus the cecum may remain on the left side or under the ensiform or in the neighborhood of the gallbladder. These faulty positions may not of themselves be important or disturbing to the normal function of the bowel. It is only when there is a faulty position that pressure on one part or another of the bowel is likely to develop. Obstruction occurs and the condition becomes of importance necessitating relief by surgical intervention. In instances in which the development has been arrested before the parietal and visceral peritoneum were fused the mid gut remains attached to the posterior abdominal wall by only a very small area at the origin of the superior mesenteric artery. Under these circumstances a volvulus of the mid gut is particularly liable to develop. The twisting of the mid gut on itself with the origin of the superior mesenteric artery as a pivot is more likely to take place in a clockwise direction and may go

through an arc of 360 degrees or more. Of course the more it twists the more complete is the obstruction and the greater the interference with the blood supply of the bowel.

Symptomatology—The symptoms of the conditions found resulting from faulty rotation or volvulus of the mid gut are those of intestinal obstruction, namely vomiting, pain, restlessness and evidence of shock and dehydration. These symptoms may appear soon after birth or in contrast to congenital atresia and stenosis may not appear for months or even years and may be intermittent in character and of variable severity.

Fig 553.—Drawing showing the obstruction and distention of the duodenum caused by the mesenteric attachment of an unrotated and undescended cecum.*

On examination abdominal distention and visible peristalsis are noted. It is to be remembered however that the obstruction takes place most commonly in the duodenum so that the distention is less marked than in other forms of intestinal obstruction lower down in the intestine. If the patient is not too acutely ill a barium enema with roentgen examination may be used to confirm the diagnosis. In the still less severe cases a barium meal and series of roentgen examinations may yield useful information.

Treatment—The treatment of these conditions is surgical. The operation may be one of the most confusing of abdominal operations and cannot be successfully carried out unless the embryologic development is

*Ladd, Pennsylvania M J 34

kept in mind and operation is performed with a view to restoring normal physiologic function regardless of normal anatomical relations. Acidosis and dehydration are relieved preoperatively. In a case without volvulus the obstructed point is identified by the distended bowel above and the collapsed bowel below it. Suitable measures are taken to relieve the obstruction. In a case of volvulus of the mid gut the whole mid gut must be delivered out of the wound in order to ascertain the direction of the twist. The volvulus is then untwisted until no interference with circulation is apparent. The duodenum is then exposed in its entirety to insure free function and reduce the chances of recurrence. The cecum is usually placed in the left upper quadrant.

Prognosis.—In the Boston Children's Hospital there were 68 patients who had the type of operation advocated by Ladd. 58 recovered, a mortality of 14 per cent. Twelve had other types of operations, none recovered, a mortality of 100 per cent. Gangrene of the bowel and other complications were factors in the mortality in these cases.

MECKEL'S DIVERTICULUM

Definition.—The vitellointestinal duct is the communication between the mid gut and the yolk sac during the first few weeks of fetal life. Persistence of this duct or parts of it in postnatal life was first described by Meckel in 1815, since which time it has been known as Meckel's diverticulum. Meckel's diverticulum arises from the free or antimesenteric portion of the ileum about 20 inches above the ileocecal valve. The persistence of this duct is estimated to occur in from 2 to 4 per cent of infants.

Pathology.—Though a Meckel's diverticulum may be present throughout life without causing symptoms it is subject to a wide variety of pathologic changes and must always be considered a potential source of danger. (1) It may remain attached to the umbilicus with a patent opening, or intestinal fistula. (2) it may remain attached to the umbilicus without a patent opening. (3) it may become detached from the umbilicus and hang loose in the abdominal cavity or its tip may become attached to some other point in the peritoneal cavity and cause intestinal obstruction. (4) it may

become the site of acute inflammation or diverticulitis. (5) in many instances it contains aberrant gastric mucosa and is prone to show ulceration with hemorrhage or perforation and (6) in some instances it inverts itself into the lumen of the ileum and acts as the advancing point of an intussusception.

Symptoms.—The symptoms caused by Meckel's diverticulum are variable according to the type of developmental error and the pathologic conditions arising from it. The patent opening at the umbilicus gives the inconvenience and annoyance of any fecal fistula with the difficulty of taking care of the fecal discharge and the irritation or digestion of the surrounding skin. The diverticulum which remains attached to the umbilicus may give intermittent abdominal pain of rather mild character referred to the umbilicus or more severe pain associated with vomiting, abdominal distention and visible peristalsis in short the signs and symptoms of intestinal obstruction. The diverticulum which is not attached to the umbilicus may become adherent to almost any point in the abdominal cavity across a loop of intestine and cause intestinal obstruction. When a Meckel's diverticulum is the site of acute inflammation the signs and symptoms are similar to those of acute appendicitis and this erroneous diagnosis is frequently made. The importance of hemorrhage from the bowel as a symptom of Meckel's diverticulum must be emphasized. It occurred in over 60 per cent of a series of cases reported by Hudson from the Children's Hospital of Boston and attention has been called to this important symptom by Mason and Graham and others. In instances in which the ulceration perforates the signs are those of peritonitis frequently preceded by a history of blood in the stools. If a Meckel's diverticulum is inverted into the lumen of the intestine causing intussusception the symptoms and signs are of course those of intussusception.

Treatment.—The treatment of Meckel's diverticulum is surgical and aimed at relieving the variety of conditions which it causes. Thus if peritonitis exists the peritoneal cavity should be drained if intestinal obstruction is present it must be relieved and when intussusception is found that must be reduced. All the operative procedures entail

removal of the Meckel's diverticulum. This should be done with a transverse incision in the ileum at the base of the diverticulum and the incision sewed up transversely so as not to obstruct the lumen of the ileum. There is always a temptation to remove a diverticulum as one would an appendix by a tie at its base and inversion of its stump with a purse string suture. This procedure should be condemned because of the probability that intestinal obstruction will result.

Prognosis—The results of operative relief of the conditions caused by Meckel's diverticulum have not been as satisfactory as they should be. Hudson reports 10 deaths in a series of 40 cases from the Children's Hospital of Boston. Recognition of the condition and earlier diagnosis with appropriate surgical relief should reduce this mortality appreciably.

DUPLICATIONS OF THE ALIMENTARY TRACT

Definition, Etiology and Pathology—The term duplications of the alimentary tract is used in the hope of simplifying the nomenclature and because it more accurately describes the condition found. Some of the terms that have been employed are mesenteric cyst, enteric cyst, enterogenous cyst, diverticulum, giant diverticulum, ileum duplex, jejunum duplex and unusual Meckel's diverticulum. All these names are used to describe the same condition and none of them is as accurately descriptive as the term duplication. In the last fifteen years my colleagues and I have had twenty-six patients with duplications in various parts of the alimentary tract. The ileum is the most frequent place for duplication to occur but the condition has been found in the jejunum, duodenum, stomach, mediastinum and tongue.

Grossly the cysts are variable in size but quite uniform in structure. A section through the wall will show a serous layer, a muscular layer and a layer of mucous membrane as in the alimentary tract. The mucous membrane may be like that of the colon, the stomach, the duodenum or the ileum. The contents of the cyst may be mucoid fluid, sometimes chocolate colored and sometimes almost colorless. In some instances

the fluid is sterile but it may contain pus cells or colon bacilli. The chemical content of the fluid has been found similar to the succus entericus found in an isolated loop of bowel.

Symptomatology—The symptoms vary according to the size and the situation of the malformation. When the cyst is in the chest, it causes coughing, cyanosis or dyspnea. If it is in the abdomen, there is pain and symptoms of acute or chronic intestinal obstruction are evident. Hemorrhage from a peptic ulcer of the lining of the duplication may take place and may be sufficiently profuse to be alarming or fatal. Perforation with attendant peritonitis has also occurred. A correct preoperative diagnosis is seldom made. It may be difficult to differentiate between Meckel's diverticulum, intussusception, an omental cyst and intestinal obstruction resulting from other causes.

In all our cases in which duplication occurred in the abdomen, vomiting was a prominent symptom. Mild pain or abdominal discomfort was present in all and under nourishment or feeding difficulties were usually a part of the picture. Most of these patients had been treated as feeding problems.

The blood found in the stools may come from a peptic ulcer next to misplaced gastric mucosa in the lining of the duplication or from congestion of the intestine by pressure of the cyst. The tumor may usually be felt and is likely to be rather more mobile than tumors of other origin. Roentgen examination of the abdomen is sometimes helpful but often is not. In one instance it showed free air in the peritoneal cavity denoting perforation and in one instance it showed pressure on the stomach and on the colon. It may demonstrate partial obstruction which of course can be diagnosed by other means also.

From our experience duplication of the alimentary tract should be suspected in a child suffering from symptoms of partial intestinal obstruction in whom a freely movable tumor may be felt. It should be suspected also when blood is found in the stools when the symptoms are less acute than those of intussusception and when the tumor is larger than one would expect in a case of Meckel's diverticulum.

Treatment—The treatment of this condition is of course surgical and on account of the danger of obstruction perforation or hemorrhage the operation should not be unduly delayed. The operative technique is of importance and usually involves resection of the loop of the bowel to which the cyst is attached. It is a temptation for the surgeon who meets one of these cases for the first time to attempt to dissect the duplication away from the normal bowel. It is unwise to do this except in the rare case in which the duplication is detached from the normal bowel and has a mesentery of its own. In the usual case the blood supply of the duplication and the blood supply of the bowel to which it is attached are the same and if one dissects the duplication the blood supply of the bowel is destroyed. Another reason it is unwise or indeed impossible to dissect the duplication from the normal bowel is that there is no line of cleavage between the two. The partition between them consists of two layers of mucous membrane with the muscle layers between and it is almost impossible to separate them without perforating the lumen of one or both.

Prognosis—If operation is undertaken prior to the occurrence of infection perforation or severe hemorrhage the risk is not great and the results are gratifying.

INFECTIONS AND TUMORS OF THE SMALL INTESTINE

The apparent freedom of the small bowel from disease is remarkable. It is seldom mal-formed and seldom the site of tumors. Its two outstanding infections, tuberculosis and typhoid, are nowadays rare. Obstruction is the chief disorder to which it is subject. Apart from these disturbances of its function are assumed to be infrequent, at least their presence is seldom considered in the differential diagnosis of abdominal disease. It is possible, however, that dysfunction of the small bowel causes more trouble than has been ascribed to it. It would seem unlikely that an organ which performs so vital and complicated a function as digestion and absorption of food should be the seat of little or no trouble. There is reason to suspect that its disorders are often the cause of symptoms erroneously attributed to cholecystitis, chronic appendicitis, nervous indigestion, etc., and that grave disturbances of metabolism are caused by its failure to absorb vitamins or other essential substances from food. The recent literature shows a growing interest in this subject. The technique of roentgenologic examination of the small intestine has recently been greatly improved by the use of injections of contrast media through the Miller-Abbott tube. This permits demonstration of tumors and other lesions which heretofore could be discovered only at operation or autopsy. Roentgenologists can now recognize with ease a characteristic dysfunction of the small intestine due to lack of the vitamin B complex, which may be noted with sprue, celiac disease, or states of inadequate nutrition. Recognition of this condition is of great importance in the preparation of patients for operation and in the postoperative care of patients who are unable to take an adequate diet. The x-ray picture shows hypomotility of the small intestine with puddling of the barium content and irregular segmentation of it. Campbell has recently reviewed this subject.

NON-SPECIFIC INFECTIONS

From the time the infant begins to take food the small intestine contains bacteria. The forms present are few in the nursing infant but become more numerous when a

general diet is taken. Years ago Harvey Cushing showed that in the fasting state the duodenum is practically sterile and that the number of bacteria increases from duodenum to ileocecal valve where it is very great. It is doubtful if the normal bacterial inhabitants of the human intestine aid digestion though bacteria in the intestines of her livestock do so by breaking down cellulose. Furthermore it is doubtful if bacteria in the human intestine do harm except when the bowel has been injured in some way. Injury to the bowel followed by infection may be caused by (1) debilitating systemic disease (2) achlorhydria gastrica or gastroenterostomy—conditions which cause too rapid emptying of the stomach (3) intestinal obstruction, which produces anemia of the bowel by overdistention or by interference with its mesenteric circulation and (4) parasites which penetrate the mucosa.

Normally the food passes through the small bowel so rapidly that it is difficult to believe that bacterial action in the intestinal contents can be very great until the food enters the large intestine. Some pediatricians have expressed the view that bacteria in the small bowel may produce a serious ascending infection of the duodenum and stomach of a child in whom achlorhydria has developed because of some systemic disease. It is possible that the diarrhea which often follows in a day or two the relief of an intestinal obstruction is due to an infection of the small bowel. Infection of the small bowel can cause diarrhea by interfering with the proper digestion and absorption of food, the result being that undigested food is poured into the large bowel.

Mesenteric lymphadenitis is best considered under the heading of non specific infections of the small bowel. The most common pathologic finding at laparotomy is enlargement of the mesenteric lymph glands. Hundreds of these ranging from the size of a large almond to that of a grain of wheat sago like in appearance may be seen studying the entire mesentery of the small bowel. Mesenteric lymphadenitis is always associated with enlargement of the retroperitoneal glands. The writer in common with others has subjected great numbers of these glands to microscopic examination and has found almost always simple hyperplasia without

evidence of tuberculosis. Mesenteric lymphadenitis is most common in young patients but is not uncommon in patients of any age. It is most marked in the glands of the lower ileum. It is often the only evidence of intra abdominal disease found at exploratory laparotomy. It is noteworthy that no observable abnormality of the intestine usually accompanies it.

The etiology of non tuberculous mesenteric lymphadenitis is unknown. Infection of the intestine and the presence of intestinal parasites have been suggested as causes but no evidence of the presence of either can be found in the vast majority of cases. It is by no means certain that the lymphatic hyperplasia is due to infection at all. The glands have almost always been found to be sterile. It is possible that the most common cause is the absorption of incompletely or improperly digested protein material from the bowel. It is a common observation that injections of foreign proteins can cause enlargement of lymph glands. Infection however is the cause in some cases because suppuration of the glands has been observed. Certain authorities have attributed mesenteric lymphadenitis to appendicitis. The experience of the writer supports the idea that appendicitis is the most serious and most common complication of mesenteric lymphadenitis. If this is true then both would seem to be due to the same cause namely something which stimulates hyperplasia of the lymphoid tissue. There is a large quantity of lymphoid tissue in the submucous coat of the appendix. Hyperplasia of this tissue will block the lumen of the appendix thereby causing its distention and interference with its blood supply.

The clinical symptoms said to be associated with mesenteric lymphadenitis are (1) pain usually in the right iliac fossa (2) more or less generalized abdominal tenderness on pressure but without muscle spasm (the area of maximal tenderness is often in the right iliac fossa), (3) occasional fever, usually of from 1° to 2° F., (4) moderate leukocytosis (5) flatulence (6) dyspepsia (7) and general malaise and nervous instability. It is obvious that these symptoms are liable to be interpreted as due to appendicitis, nervous indigestion, hyperacidity, cholecystitis etc. The differential diagnosis from

subacute appendicitis cannot be made. The outlook is favorable. This subject is worthy of further clinical and experimental study.²

SPECIFIC INFECTIONS

Under this heading are included (a) typhoid fever (b) tuberculosis and (c) regional ileitis.

Regional ileitis presents a definite pathologic picture but is of unknown etiology. The writer has been unable to find a report of primary actinomycosis of the small intestine. Syphilis occurs rarely in the jejunum of infants and also rarely at the ileocecal valve in adults. Asiatic cholera, bacillary dysentery and amebic dysentery (which may involve the terminal ileum) are not within the scope of this discussion.

Typhoid fever affects the lymphatic follicles of the intestine. For this reason the lesions occur chiefly in the ileum and are most numerous near the ileocecal valve. The follicles become swollen early in the course of the disease. The surgeon can easily recognize the presence of the enlarged Peyer's patches by the elevated and hyperemic areas they produce on the peritoneal surface of the bowel. They may undergo either resolution or necrosis and sloughing. In the latter case ulcers result which are ovoid or irregular in shape, having their long axes parallel to the long axis of the bowel and having the submucosa, the muscularis or even the peritoneum as a base. It is the sloughing of Peyer's patches which causes the surgical complications of typhoid fever—hemorrhage and perforation. Both occur at the time of separation of the sloughs, usually in the third week of the disease.

The diagnosis of perforation of the bowel due to typhoid fever depends chiefly on the occurrence of a sudden sharp abdominal pain usually in the lower part of the abdomen and to the right of the midline. This is followed by tenderness on pressure and muscle spasm. The patient also shows signs of shock with an increase in the pulse rate and a drop in temperature. Vomiting may or may not be present. Later the signs of general peritonitis appear. This picture may be obscured or absent in a profoundly toxic patient. Perhaps the most important rule to observe in making the diagnosis is to *watch every patient with typhoid fever constantly*

and carefully for suspicious abdominal symptoms. Laboratory tests are of but little help. In doubtful cases it is safer to operate at once than to worry too long over the diagnosis. These patients endure operation remarkably well and laparotomy seems to exert a curative effect on the disease.

Typhoid fever has become so rare that the present generation of surgeons has had but little experience in treating its complications. At the Indiana University Hospitals from 1914 to 1934 in 76,518 admissions there were 222 cases of typhoid fever and 2 cases of perforation of the bowel due to typhoid fever.

Operation to be effective must be performed early. Either local or general anesthesia is used and a low short right rectum incision is made. All free intestinal contents are carefully removed by aspiration. The terminal ileum is explored for the perforation which will usually be found within a few feet of the ileocecal valve. If it is small it may be closed with fine silk. If it is large or if numerous ulcers on the point of perforation are found it is best to resect the entire piece of involved ileum and bring the ends of bowel out as a gun barrel enterostomy. Surgeons of the past generation emphasize the poor healing of wounds in typhoid patients. They observed that the wound would remain for days without showing any signs of granulation. It is known now that this trouble was due to avitaminosis and the starvation treatment. It should not occur in the patient treated according to modern methods.

Intestinal hemorrhage in typhoid fever is also due to sloughing of Peyer's patches and usually occurs in the third week. The symptoms are those of internal hemorrhage—rather sudden pallor, acceleration of the pulse rate, a fall in the temperature, restlessness followed by torpor and with large and sudden loss of blood in hunger. Sooner or later blood appears in the stools. The sudden pain characteristic of perforation is absent though it may be simulated by tetanus. Perforation may accompany hemorrhage. It should be mentioned that there will be no immediate change in the blood count or hemoglobin value.

Treatment consists of (1) withdrawal of all food by mouth, (2) intravenous admin-

istration of salt solution and glucose in quantities sufficient to meet the physiologic needs of the patient (it is doubtful if this will increase or reactivate the hemorrhage if care is used) and (3) blood transfusion if the loss of blood has been great. Morphine may be necessary to control restlessness but should be used with caution because of the danger of masking symptoms.

Tuberculosis—Tuberculosis may invade the walls of the small bowel from its peritoneal or from its mucosal surface. In tuberculous peritonitis the infection may penetrate to the lumen of the intestine or it may so weaken the bowel wall that it easily ruptures when adhesions are being freed at operation. When the infection attacks the mucosa it localizes as does typhoid fever in the lymph follicles. Unlike typhoid however it usually produces fibrosis of the surrounding tissues and of the lymphatic vessels draining the ulcers. Since these vessels encircle the bowel their contraction as a result of fibrosis causes a narrow constriction of the bowel as though a cord were tied around it. Multiple constrictions of this kind make the intestine resemble a string of sausages.

The diagnosis of the mucosal form of intestinal tuberculosis is easy to make if the condition complicates pulmonary tuberculosis. It sometimes occurs when pulmonary lesions are apparently inactive or absent. Fever, diarrhea with a little blood in the stools, loss of weight and in advanced cases signs of obstruction should lead to careful examination of the stools and roentgen examination of the intestine. In the absence of perforation or of obstruction the treatment is medical. Patients in whom obstruction develops have the disease in the dry or sclerotic form. Excellent results are obtained from resection of the involved portion of bowel.

Regional Ileitis—Crohn, Ginzburg and Oppenheimer^{3,4} in 1930 first called attention to regional ileitis as a clinical entity. They described it as a granulomatous inflammation of unknown etiology involving the terminal part of the ileum. It is characterized morphologically by thickening of the bowel wall by ulceration of the mucosa and in some cases by perforation of the bowel or the formation of fistulas into contiguous loops of intestine. Clinically it is

characterized in general by abdominal pain, fever, diarrhea, anorexia, loss of weight and strength and vomiting and sometimes by obstruction sometimes by peritonitis due to perforation and always by a chronic course. It is not always cured by resection of the involved segment of bowel. When it is complicated by fistula or obstruction a palliative operation should be done before resection is undertaken. Spontaneous cure occurs in some cases. Brown, Bergen and Weber report 18 cases of regional enteritis. They state that the disease may attack the jejunum, the ileum or the proximal portion of the colon. Though the literature on regional ileitis is now extensive the etiology is still unknown.

TUMORS OF THE SMALL INTESTINE

A *Benign tumors* of the small intestine are very rare but of rather numerous varieties. Lipoma, myoma, adenoma, adenomyoma, fibroma, angioma, pancreatic rests, cysts and various kinds of polypi have been observed. They may grow into the lumen of the bowel or outward beneath the peritoneum. They often start in intussusception. Certain of them, e. g., angioma and myoma may cause great loss of blood. Colicky pain seems to be the earliest symptom. Blood may be present in the stools. The physical findings are those of partial or complete intestinal obstruction. A palpable mass may or may not be present. Roentgen examination with a barium meal if obstruction is not complete or by means of a flat plate showing the intestinal gas patterns if it is complete is of value. The diagnosis has usually not been made before laparotomy performed to relieve obstruction. Treatment is of course resection of the portion of bowel containing the tumor.

B. Malignant tumors also are rare. They are of three kinds: (1) adenocarcinomas, (2) carcinoids and (3) sarcomas.

1 Adenocarcinoma of the small intestine very seldom arises in polypi according to Fung. Its most common location is near the ampulla of Vater. There it causes jaundice, the pancreatic form of diarrhea, rapid emaciation and in some cases symptoms resembling those of pyloric obstruction. In the jejunum and ileum it causes progressive obstruction and anemia. Rankin and Mayo⁵

report 55 cases observed at the Mayo Clinic. The youngest of the patients was thirty-two, the oldest sixty-nine. The average age was forty-seven and one-half years. Typical findings on physical examination were visible peristalsis, loud borborygmi, and sometimes a palpable tumor. The roentgenographic study was a valuable aid to diagnosis. The results of resection were almost totally bad because of the early presence of metastases.

2 Carcinoid (see section on Ganglioneuromas) —The name carcinoid has been given to a remarkable tumor which may develop anywhere in the intestinal tract but is found most often in the appendix. Its next most frequent site is the small intestine. It has a distinctive and easily recognizable histologic appearance, superficially resembling basal cell cancer. Its cells contain granules which reduce a solution of ammoniacal silver; hence they are called argentaffin. They stain with chromic acid and are therefore chromaffin. Their histogenesis has been the subject of much study and dispute, and there is still no general agreement about it among authorities. An endodermal, a mesodermal, and an ectodermal (neurogenie) origin have been attributed to them. The subject is too complicated and technical to be discussed here. Reference should be made to the paper by Cooke⁷ for a complete presentation of the entire subject of carcinoid.

The following facts concerning the clinical features of carcinoid of the small bowel are of importance:

(1) The tumors are usually small, submucosal nodules, yellowish or grayish on section, but they may be annular growths which obstruct the bowel. They are often multiple in origin.

(2) Their most common site is in the terminal ileum.

(3) About 20 per cent of carcinoids of the small bowel produce metastases in the lymph glands and liver. They are therefore liable to be more malignant than adenocarcinomas of the appendix, which do not metastasize beyond the regional lymph nodes.

(4) The average age incidence in the reported cases is about fifty-five years. The tumor is slightly more common in males.

(5) Though carcinoid is a rare tumor, it should be considered as a possible cause of obstruction of the small bowel.

3 Sarcoma —Lymphosarcoma is the most common form of sarcoma of the small bowel, though almost every known form of sarcoma has been found there. About 200 cases have been reported to date. It occurs at all ages of life, having been observed in a child of three years. It is about twice as common in males as in females. It has no characteristic clinical picture, though writers report certain fairly constant features, namely, intestinal disturbance, rapid loss of weight, and rapid development of anemia. Its progress is usually more rapid than that of cancer of the bowel. Lymphosarcoma is liable to cause obstruction because its growth is usually less fibrotic and less liable to involve the entire circumference of the bowel. It is more liable to cause perforation of the bowel than is cancer. It is said to be less liable to cause intestinal hemorrhage. Metastasis is of course more widespread and earlier than in cancer. The tumor is likely to become fixed to surrounding structures by adhesions.

The diagnosis has probably never been made with certainty before operation or autopsy. A careful roentgen study of the small bowel may reveal the presence of some form of tumor of the bowel, and a careful consideration of all the clinical data may lead to a diagnosis of sarcoma.

The prognosis of sarcoma of the intestine depends on the histologic character of the tumor. Cure of fibrosarcoma has been reported. Unfortunately the outlook for the form usually found, lymphosarcoma, is almost hopeless, though roentgen therapy may give good immediate results.

The treatment is resection of the involved piece of bowel and of a wide area of mesentery, followed after operation by deep roentgen therapy.

APPENDICITIS

Definition.—Acute appendicitis is essentially a bacterial infection involving the appendix a part or the whole of which may be affected. Appendicitis is common. There are however certain nomad tribes in which the disease is rare. The restraints placed on the proper exercise of bowel function in civilized life may account for its greater frequency among certain peoples. The symptoms of appendicitis are usually well defined and clearcut but there are cases that are not easily diagnosed. The commonness of the disease should offer an incentive to every physician to possess thorough knowledge of it. If he approaches each suspected case of appendicitis with the purpose not merely of making a diagnosis but also of committing himself to a prediction as to the location and exact pathologic condition of the appendix, appendicitis will prove to be a disease of unending interest.

Historical.—Appendicitis should have been recognized as a clinical entity long before 1886 when Reginald Fitz of Boston recognized it and aroused the profession to take an active interest in it. A century ago attention had been drawn to the fact that inflammation occurs in the appendix. Meibner in 1759 is credited with being the first to publish such an observation. In 1812 Parkinson attributed a case of fatal peritonitis to a perforated appendix. Twelve years later Lousier & Hermann described a case of gangrenous appendicitis in which there was no concurrent inflammation of the cecum. A carefully thought-out paper was presented in 1839 by Meier based on 5 cases and he emphasized the probable frequency of the condition. Meier is believed to have been the first to recognize a case of appendicitis during life. Unfortunately his conclusions were rejected by the great authorities of the day. Dupuytren. This famous surgeon attributed abscesses and peritonitis arising in the right side of the abdomen to inflammation of the cecum which he called perityphlitis. Krunkle in 1881 was the first surgeon to recognize a case of peritonitis due to perforation of the appendix and to remove this organ.

Anatomy.—The length of the vermiform appendix may vary from 3 to 20 cm and the thickness from 3 to 15 mm. But far more important is a realization that this structure may be in any one of nine different positions. These are in their order of relative frequency: (1) into the pelvis; (2) along the iliac vessels; (3) to the promontory of the sacrum; (4) posterior to the cecum; (5) under the ileum; (6) lateral to the cecum; (7) into the iliac fossa; (8) among the coils of small intestine; and (9) medial to the cecum (Fig 554).

Incidence.—Acute infection of the appendix may occur at any age. The earliest case reported was in an infant three days old. The author has operated on an appendiceal abscess in a patient who was in the nineties. It is however in the second and third decades of life that the disease occurs most frequently and it is generally agreed that men are affected somewhat more often than women. Likewise there is unanimity of opinion regarding the relative frequency of appendicitis among highly civilized and primitive peoples. The latter group seldom suffer from this ailment as long as they are untrammelled by the restrictions of civilization. It seems clear that dietary habits lack of physical exercise and modes of living which restrict the natural tendencies to frequent and complete defecation favor the incidence of appendicitis. Thus it follows that cases are more common in an urban population than in a rural one. Similarly they are seen more often among European Turks who eat meat in large amounts than among Asiatic Turks who subsist on bulkier food. Likewise troops who engaged in actual field maneuvers were found to have a low incidence of appendicitis whereas the same group of soldiers while confined to the sedentary life of a cantonment had a high incidence. In the Orient the disease is astonishingly infrequent and the author ventures to suggest that the posture assumed by Orientals when defecating accounts for this fact. In the East natives squat when defecating. This posture forcefully flexes the thighs on the abdomen and thus tends to empty the cecum completely. There are no accurate data to show that real appendicitis is more frequent among wealthy persons than among the poorer classes. The question has been

raised concerning familial predisposition inasmuch as sometimes several members of one family have suffered attacks of acute appendicitis. The probabilities are however that similarity of diet and habits is a more likely explanation of such occurrences.

Finally the steadily rising incidence recorded in vital statistics is misleading and probably incorrect. The diagnosis is surely made more often than formerly. The number of appendectomies increases each year but such a state of affairs is no proof that the incidence of acute infections in the appendix is greater now than it was twenty years ago.

of men are distinctly different. Consequently most of our knowledge concerning the causative factors of appendicitis has been gained from a study of the various pathologic alterations observed in appendices removed at different stages of the disease. Our only other sources of information relative to the etiology of appendicitis are clinical observations and bacteriologic studies.

The appendix is the most likely part of a normal gastrointestinal tract to become infected for it is a blind pouch with a relatively narrow lumen. Any mechanical factor which interferes with the discharge of mucus through the lumen into the caecum produces

Fig. 51—Diagram showing the possible positions of the appendix (Kelly Hirsch).

Etiology—In the consideration of this subject it is wise to comment separately on primary and recurring attacks of appendicitis for it seems likely that additional causative factors are operating after an initial attack. It is wise too for the student to realize that efforts to produce and to study the disease experimentally have been unsuccessful. This is largely due to the fact that no experimental animal possesses a vermiform appendix that is like the human appendix.* Moreover the intestinal flora of animals and

stasis and distention which in turn decrease the vascularity of the organ and thereby facilitate the growth of pathogenic bacteria. When one stops to think of it it is surprising that the disease is not much more frequent than it is. There are doubtless great numbers of mild cases that are cured spontaneously by hyperperistalsis of the appendix. Similarly most initial attacks are probably not reported to a physician and unrecognized as appendicitis. Consequently it is always difficult to be certain that a particular attack is actually the primary one. When one realizes the vast numbers of pathogenic bacteria in the caecum it seems incapable that most primary cases of appendicitis must result from a backing up of

* An instructive series of diagrams illustrating the comparative anatomy of the ileocecal region is found in Kelly and Hirsch's classic book entitled *The Vermiform Appendix and Its Diseases* published by W. B. Saunders Co. in 1901.

infected material from the cecum into the appendix. This belief is supported by pathologic studies of appendices removed shortly after the onset of symptoms for in such cases the lesion is invariably found in the interior of the organ with no evidence of infection on the peritoneal side. Aschoff believes that the actual site of the beginning of the inflammatory process is in the depressions and pits of the mucous membrane where mechanical factors are conducive to the growth and penetration of bacteria. There must of course be a small break in the mucous membrane which is covered quickly by a bit of fibrin and leukocytes. The inflammatory reaction spreads in a wedge-shaped manner from this focus and may subside or may progress to the formation of an intramural abscess. Such an abscess in turn may resolve or may rupture either into the lumen causing ulceration or into the peritoneal cavity. Whether there are cases in which the passage of bacteria through the mucous membrane depends on lowered vitality (resistance) of the patient rather than on trauma of the mucous membrane seems improbable since clinically one does not see the disease occurring more frequently in patients who are sickly than in people who are in vigorous health. Another etiological factor is a change in the type or in the virulence of the bacteria lodging in the lumen of the appendix for in many cases there is no localized site of inflammatory reaction but a widespread diffuse involvement of the entire mucous membrane. The lining of the lumen is fiery red and swollen. This is the lesion one is likely to see when appendicitis comes on as an extension of acute colitis.

In some cases an enterolith is unmistakably an etiological factor. These concretions are either balls of inspissated mucus, bacteria and cellular debris or particles of fecal matter covered over with mucus. Fecal matter as such is seldom seen in a normal appendix as this structure is constantly secreting mucus and actively discharging it into the cecum. Authorities disagree as to the actual role which enteroliths play in the causation of appendicitis, not infrequently at autopsy a normal appendix is seen to contain this concretion. On the other hand it is exceedingly common at operation to find the

lumen of an appendix occluded by a large enterolith and distal to this the tissues engorged and infected whereas proximally they are normal. Enteroliths frequently cause pressure necrosis with resultant ulceration and perforation. One statistical study reports the occurrence of such destructive lesions in 85 per cent of the cases with enteroliths. Aschoff however has recorded an unusual instance in which the entire appendix was gangrenous except the area beneath a large enterolith.

An important etiological factor is stenosis or occlusion of the lumen of the appendix. This may be due to a scar resulting from a previous infection to congenital peritoneal bands to postinflammatory peritoneal adhesions or to sharp kinking of the appendix. Whenever complete occlusion of the lumen occurs one is likely to find a distended distal portion. Frequently there is little or no active infection and one has the feeling that the condition is simply a mechanical one.

Bacteriology.—The bacteriology of acute appendicitis is not clearcut and distinct. Cultures of a variety of pathogenic organisms have been made from the areas of infection. Only cultures made at the time of operation and carefully worked up are of any significance for colon bacilli quickly overgrow other bacteria. It is not surprising therefore to learn that in nearly all the early studies on this subject the colon bacillus was assigned the predominating role as etiologic agent. More recent work has emphasized the significance of streptococci. Hiram considers these organisms as the most frequent infecting agents of acute appendicitis. He obtained streptococci in pure culture in 16 of 23 cases. Oberndorfer holds the same opinion. Whether or not colon bacilli alone can cause severe infection in the appendix is an important problem that has not yet been solved. Whenever streptococci are solely responsible for acute appendicitis one finds thin scanty odorless pus whereas in those cases that are due to a mixed infection or to colon infection there is thick foul smelling pus. There are moreover other differences due to the prevailing bacteria. Mixed infections tend to quick invasion and early gangrene streptococcal infections are said to occur predominantly in young patients while colon infections are seen usually in elderly ones.

an indispensable feature of appendicitis. Actually one finds tenderness and spasm at McBurney's point only when the appendix happens to lie beneath it. Absence of this sign therefore does not minimize in the slightest the chance that a case is one of appendicitis. Whenever an acutely inflamed appendix is in actual contact with the peritoneum of the anterior abdominal wall there is extreme tenderness and rigidity of the overlying muscles. When the offending organ extends into the pelvis there may be no muscle spasm and the only point of tenderness is that detected on making a pelvic or rectal examination. When the appendix lies retroceally the maximum tenderness and muscular rigidity are posterior but seldom as far up as the costovertebral angle.

Temperature and Pulse Rate—There is nothing characteristic about the temperature curve in this disease unless it is that high fever at the onset (103°F) makes the diagnosis improbable. Absence of fever does not vitiate the diagnosis. Ordinarily it is wise to take the temperature in rectum in cases of appendicitis and it is usually found to be slightly above normal. The temperature tends to rise with the progress of the infection but there is no constant or reliable relationship. The duration of fever also varies and may be from one to several days. More important and constant are accelerations in the pulse rate. Unfortunately few patients know their normal pulse rate and unless this is established it is impossible to detect an increase of 20 or 30 beats a minute. A pulse rate of more than 110 in cases of appendicitis is very suggestive that perforation has occurred. It is most exceptional for appendicitis to begin with chill and when this symptom does occur one suspects the presence of a grave complication such as pylephlebitis. Occasionally a severe chill results when an inflamed appendix lies in apposition to the right ureter or the iliac vessels.

Gastrointestinal Symptoms—Nausea and vomiting frequently thought to be integral parts of the syndrome of appendicitis are as a matter of fact incidental and are often entirely absent. One can safely say that nausea and vomiting rarely if ever are the presenting symptoms of this disease. In some cases however severe nausea and protracted vomiting occur after the onset of abdominal

pain. A more constant symptom of appendicitis is a disinclination to eat. Seldom does a patient with an acute condition of the appendix care to eat a hearty meal. Moreover when food is taken there is often an increase in the severity of the cramps in the right lower quadrant. It was formerly said that constipation is always associated with this ailment but it is more correct to say that constipation or diarrhea or both are usually associated with it. Treves carefully questioned 48 patients and reports constipation in 26, diarrhea in 13, normal movements in only 8 and constipation alternating with diarrhea in 1. The cases beginning with severe diarrhea and generalized abdominal cramps are particularly treacherous for in these cases the evidences of appendicitis do not appear until after from twelve to thirty six hours. It seems likely that these are cases of colitis in which involvement of the appendix is secondary.

Leukocytosis—There is a growing tendency to disregard the white cell count in cases of appendicitis. A safe point of view is to regard a leukocyte count of 10,000 to 20,000 as confirmatory evidence of the disease. A differential count with an increase in the number of polymorphonuclear cells especially an increased percentage of immature forms is a trifle more suggestive. It must be remembered however that one never waits for leukocytosis before making the diagnosis of appendicitis. There are thousands of patients with acute appendicitis who have had a normal white cell count. In fact the severest infections which produce early gangrene and rapidly progressive peritonitis frequently cause no leukocytosis whatsoever.

Differential Diagnosis—*Renal and Ureteral Calculi*—Sometimes the differentiation between renal or ureteral colic and appendicitis is far from easy particularly when the inflamed appendix lies along the ureter and consequently causes the appearance of red blood cells and pus cells in the urine. The pain associated with the passage of renal and ureteral calculi tends to become maximal shortly after the beginning of an attack and continues with great severity whereas the pain of appendicitis is more intermittent owing to peristalsis and seldom begins in an excruciating manner. Furthermore in renal

colic the pain is often out of proportion to other signs and symptoms. The characteristic radiation of ureteral pain to the bladder and genitalia is often a conclusive factor in making the diagnosis. With appendicitis there is nearly always more muscle spasm than in cases of ureteral colic. Whenever there is associated pyelitis with ureteral disease it is possible to elicit the telltale tenderness in the costovertebral angle. A renal genogram will usually determine the presence of a stone although calcifications in glands are sometimes confusing.

Intermittent hydronephrosis is of interest because it is not often kept in mind and because the clinical picture can simulate that of appendicitis. The pain from hydronephrosis usually reaches its maximum intensity soon and remains there. If there is radiation it is into the groin but often the pain is dull and persistent and is localized in the flank. If an enlarged kidney is palpable or if the patient suddenly passes a large quantity of urine with disappearance of the pain the diagnosis is easy. In cases of uncertainty a pyelogram is usually conclusive.

Pyelitis—In this condition there is generally but not always pus in the urine. It must be remembered that an acutely inflamed appendix lying in contact with a ureter may cause pus cells to appear in the urine. The fever in pyelitis usually is higher and there may be lumbar tenderness and dysuria. Chills frequently result from pyelitis rarely from appendicitis.

Disease of the gallbladder is one of the most important ailments to differentiate from appendicitis. The difficulty lies in the fact that often lesions in the gallbladder do not give rise to the classical radiation of pain through the body to the tip of the right scapula. Furthermore when the liver is low or the gallbladder enlarged one may find localized tenderness at McBurney's point and vice versa a long appendix especially if it is retrocecal may give rise to pain and tenderness in the right upper quadrant. Occasionally the tip of the appendix will reach as far upward as the gallbladder. A most helpful clue in recognizing disease of the gallbladder is the history of many previous attacks. Another aid is the story of a similar attack of severe pain which entirely disappeared in a few hours. True appendi-

citis does not subside with the abruptness of gallbladder colic. In general gallbladder colic is more abrupt in its onset more severe in intensity and of shorter duration than the pain of appendicitis.

Acute Salpingitis—In a community with a large colored population and a consequently high incidence of salpingitis acute salpingitis is the most frequent and often the most difficult condition to differentiate from appendicitis. These patients often give an unreliable history of the onset of their sickness. To add to the difficulty both conditions give rise to varying degrees of fever, leukocytosis and gastrointestinal symptoms. Bilateral tenderness on pelvic examination is the most reliable differential point. The presence of a profuse vaginal discharge is helpful but not conclusive. In many cases it is impossible to be certain whether one is dealing with an abscess arising from the tubes or from an appendix lying over the pelvic brim.

Perforation of a Duodenal Ulcer—An uncomplicated duodenal ulcer rarely causes any confusion with acute appendicitis but it sometimes happens that following perforation of such an ulcer the duodenal contents gravitate along the outer side of the colon and collect in the right iliac fossa. Several hours after perforation tenderness, muscle spasm and a mass may be found over the appendix. An accurate history in these cases usually indicates the correct diagnosis.

Ovarian and Uterine Conditions—The pain produced by the strangulation of the pedicle of an ovarian cyst or uterine fibroid may be like that of appendicitis but is usually more abrupt in onset, persists without exacerbations and is often associated with moderate shock. Localized tenderness and rigidity are nearly always present and may interfere with palpation of the tumor. A fairly frequent condition that sometimes reproduces the syndrome of appendicitis is that due to rupture of a cyst of a graafian follicle. This occurs ordinarily about two weeks after menstruation and causes cramp-like pain, fever and leukocytosis. A similar picture may occur with rupture of a corpus luteum at or near the time of menstruation. Gastrointestinal symptoms, localized abdominal tenderness and rigidity are usually absent.

There are a large number of other diseases that may produce a clinical picture which can be mistaken for that of appendicitis. Some forms of tuberculous peritonitis can give the signs and symptoms of an appendiceal abscess. Diaphragmatic pleurisy and even pneumonia particularly in children can be exceedingly difficult to differentiate from intra abdominal conditions. The character and rate of respiration, physical findings and roentgen examination of the chest will be helpful in these cases. Patients with illnesses due to typhoid and paratyphoid organisms are sometimes erroneously operated on for appendicitis. In these cases however the degree of fever, the bradycardia and the leukopenia are of some diagnostic value. Acute lymphadenitis frequently gives signs and symptoms identical with those of acute appendicitis. The presence of preceding inguinal adenitis or of injury to the skin overlying the right lower extremity arouses a suspicion of this condition. Acute lymphadenitis is particularly likely to occur in children. Incomplete intestinal obstruction, ruptured ectopic pregnancy, subacute pancreatitis and abscess of the abdominal wall are occasionally mistaken for appendicitis. An acutely inflamed Meckel's diverticulum gives the identical signs and symptoms of appendicitis and should be looked for at operation whenever the appendix does not show pathologic changes that are in keeping with the clinical picture.

Complications.—Abscess.—There are no complications of acute appendicitis as long as the infection is within the appendix but once the organisms reach the peritoneal surface serious and far reaching complications may develop. The commonest of these is the development of an abscess about the appendix. Naturally the evidences of such an abscess depend on the position of the appendix. The most frequent site is between the cecum and the anterior abdominal wall. Such abscesses often reach considerable size and cause a visible fullness in the right lower quadrant. Occasionally if the tip of an inflamed appendix extends to the midline an abscess forms on the left side of the abdomen being directed there by the root of the mesentery. Not infrequently an appendix reaching into the pelvis gives rise to an abscess that is indistinguishable from a tubo-ovarian abscess

and can be detected only on rectal or vaginal examination. When a retrocecal appendix forms an abscess the pus may rupture spontaneously into the ascending colon but is more likely to extend upward and lead to the formation of a subphrenic abscess. Occasionally an abscess forms as a postoperative complication and makes itself known by continued fever of a more or less hectic type.

Peritonitis.—Whether or not a patient has the ability to wall off a perforated or gangrenous appendix depends on factors that are not clearly understood. It seems however that hyperperistalsis induced by catharsis frequently prevents localization and leads to diffuse peritonitis. Clinically one suspects this complication from the patient's pulse rate and from the widespread abdominal tenderness. The latter sign appears earlier and is more constant than rigidity of the entire abdominal wall. Soon however the hippocratic facies and abdominal distention make the diagnosis obvious. In patients with peritonitis paralytic ileus often develops which is evidenced by great distention, obstipation, vomiting of large quantities of black fluid and signs of circulatory collapse. Many patients with peritonitis recover following removal of the appendix and drainage of the abdominal cavity. Few patients with well developed paralytic ileus recover.

Peritoneal Adhesions.—A late and often very serious complication of appendicitis is intestinal obstruction due to postinflammatory or postoperative adhesions. The more extensive the infectious process the greater the probability of adhesions.

Subphrenic Abscess.—Whenever there is perforation of the appendix but particularly when this structure lies retrocecally the infection may extend upward and localize in the right subphrenic space. Persistent high fever, septic in type is often the first clue to the existence of such an abscess. The physical signs of such a condition are sometimes difficult to demonstrate and it frequently happens that a roentgenogram which shows a high diaphragm on the right side is earlier confirmatory evidence than the physical examination. At times the roentgenogram will show gas between the liver and the diaphragm. In any case of doubt aspiration of pus should be attempted (See section on Subphrenic Abscess.)

Suppurative Thrombosis of the Portal Vein (Pylephlebitis)—One cannot be certain how often this complication develops, for probably some patients recover without operative treatment. Whenever a patient with appendicitis or during convalescence after appendectomy has a chill and fever, one suspects suppurative pylephlebitis. The writer has observed a case in which symptoms developed twenty-four hours after removal of a gangrenous appendix. In another instance the patient had a severe chill at the beginning of the fourth recurrence and subsequently died of pylephlebitis. Usually

monary infarct, and hemorrhage or purulent effusion follows, depending on the number and variety of bacteria present.

Treatment.—There is only one treatment for acute appendicitis—to operate as soon as the diagnosis is made, for the symptoms do not always accurately indicate the character or extent of the infectious process. It must be remembered that perforation can occur within a few hours after the initial symptoms, and the most virulent infections progress the most rapidly. To delay operation is to invite unjustifiable complications and death. It is unpardonable to give opiates

Fig. 555.—Incisions commonly used for appendectomy: a, McBurney; b, Fowler; c, Lennander; d, Battle; e, median incision used particularly for the exploration of the pelvis in conjunction with appendectomy.

the liver becomes enlarged, and chills and fever persist. Jaundice or at least a subicteric tint is seen. Aspiration of the liver at operation often fails to reveal pus, because of the occurrence of milary abscesses rather than a single large one.

Pulmonary embolism is an occasional complication of appendicitis. The emboli result from thrombosis of the veins of Retzius or of those in the pelvis or extremities. In some cases the infected appendix is adjacent to the vein, and this position accounts for the thrombosis. Smaller emboli make themselves known by pleural pain and bloody expectoration. A friction rub develops over the pul-

monary cathartics in an illness that is even suspected of being appendicitis. If, as occasionally happens, immediate operation is impossible, then absolute rest of the body and of the gastrointestinal tract (starvation and morphia) and cold applications to the right lower quadrant offer the best chances for subsidence or localization of the infection. The choice of anesthesia, the type of incision and the postoperative care are details for each surgeon to decide for himself.

When a patient is seen after an attack has spontaneously subsided (so-called "interval appendicitis"), it is good judgment to advise removal of the appendix. In some cases when

the patient is not seen by a physician until the third or fourth day of the illness it is debatable whether or not an immediate operation should be performed since at that time operative intervention may break through a partially localized infection and lead to peritonitis.

Operations.—When describing the operative treatment of appendicitis it is necessary to discuss separately the handling of

conditions and the operations are planned so as to afford access to the organ without weakening the abdominal wall. Naturally any operation that is done as often as appendectomy is will have required a variety of technical modifications many of which are of no particular merit. A simple and popular method of appendectomy is the following.

A diagonal incision is made in the right lower quadrant (Fig. 555). The level and

Fig. 556—Exposure of the cecum and appendix through a McBurney incision and the initial steps in an appendectomy.

ruptured and unruptured appendices. For the sake of clearness it is advisable to consider the subject under three headings: simple appendicitis, the perforated appendix with localized peritonitis or abscess, and acute appendicitis with diffuse peritonitis.

The first group includes all cases in which the inflammatory process, whether recent or old, is confined to the appendix. The removal of this structure is carried out under aseptic

conditions. The length of this incision varies according to the position of the appendix and the thickness of the abdominal wall. The incision is carried down to the fascia of the external oblique muscle, which is incised parallel to the direction of its fibers. Similarly, the muscle bundles of the internal oblique and of the transversalis are separated parallel to their course. No muscle fibers are cut across. By gentle traction the opening in the mus-

cles is enlarged. The peritoneum underlying the transversalis is then loosened by digital dissection so that it bulges into the wound. The peritoneal cavity is carefully opened and the cecum and appendix are brought up into the wound (Fig 556). The mesoappendix bearing the appendicular artery is clamped, divided and ligated. A purse-string suture is placed about the base of the appendix and the surrounding tissues are covered with gauze pads. A peritoneal cuff is reflected near the base of the appendix which is then crushed, ligated, clamped and divided (Fig 556). The stump of the appendix is sterilized with tincture of iodine, the gauze pads are removed and the stump is carefully inverted into the cecum (Fig 557). The purse-string suture is drawn taut and tied (Fig 557). Any raw areas in the mesoappendix are turned in and the closure of the

adhesions the operator must divide these structures carefully. In many such cases it is necessary to deliver the appendix by beginning the dissection of the mesoappendix at the cecum and continuing out toward the tip of the appendix.

The convalescent care of a patient who has had a simple appendectomy through a muscle-splitting incision presents few if any problems. The degree of nausea and postoperative discomfort is determined more by the anesthesia than by the operation. The duration of recumbency depends on the routine of the surgeon but it is customary for these patients to remain in bed for two or three days.

If a patient is seen after the infection has spread beyond the appendix but has been limited to surrounding tissues the surgeon is confronted with a difficult problem. If ap-

Fig 55 —Final steps in an appendectomy

abdominal wound is commenced by approximating the edges of the peritoneum with a continuous suture. The separated bundles of the transversalis and internal oblique muscles need little or no suturing inasmuch as every contraction of these muscles tends to bring the fibers together. The fascia of the external oblique is carefully reapproximated and the skin is closed.

In some cases a McBurney incision such as has been described does not provide adequate exposure. It is helpful then to extend the incision of the fascia of the external oblique muscle medially to the border of the rectus and to divide the sheath of this muscle so as to retract the muscle without incising it. Such a procedure is called the Weir modification of a McBurney incision (Fig 556). In those cases in which the cecum and appendix cannot be brought up because of

pendectomy is performed immediately there is the risk of breaking through the newly formed adhesions and thus causing spreading peritonitis. If the appendix is not removed the infection in it may fail to subside and may serve as the source of a serious peritonitis. No hard and fast rule can be given regarding the course to follow in such cases for there is no unanimity of opinion among surgeons. The decision to operate immediately or to postpone operation rests with the surgeon and not the attending physician. When the latter course is pursued the patient should be kept in bed and should frequently be given sedatives and nothing by mouth. Fluids can be administered per rectum or intravenously. When an abscess has formed and localization of the infection has existed for four or five days it is safe to drain the abscess and to remove the rem-

nants of the appendix. The incision that is used in such cases again depends on the judgment of the surgeon. A few urge the use of a rectus incision for an appendiceal abscess inasmuch as the incidence of postoperative hernia is considerably less when the abscess is drained through such an incision than when it is drained through a McBurney incision. Most surgeons however contend that the opening of an appendiceal abscess through a right rectus incision favors the dissemination of pus through the peritoneal cavity. (See the important comment on treatment of abscesses in the section on Peritonitis.)

The actual removal of the appendix in the presence of an abscess is carried out in the simplest manner. It is not always expedient to try to invert the stump into the thickened and inflamed cecum. The drainage of the abscess must be adequate but it is important to remember that the primary purpose of drains is to establish a tract through which pus can reach the surface consequently in a case of appendiceal abscess it is wise to allow the drains to remain in place for seven or eight days by which time they are likely to be extruded spontaneously.

Obviously the most serious cases of appendicitis are those associated with wide spread infection of the peritoneal cavity. In treating such cases the primary objective is to remove the source of the infection that is to say the gangrenous or perforated appendix. The surgeon should bend every effort to do this quickly and with as little trauma as possible to the abdominal viscera. The second purpose is to provide drainage of the peritoneal cavity particularly in the locations where pus is likely to accumulate and form abscesses therefore cigarette drains are placed beside or posterior to the cecum into the pelvis and toward the ileocecal mesentery. In some cases it is necessary to place additional drains through a small wound on the left side of the abdomen.

The advent of sulfonamide therapy has greatly altered the treatment and the prognosis of ruptured appendices. There are some surgeons who go so far as to place 6 to 8 Gm of sulfanilamide crystals in the peritoneal cavity and close it without drainage. It is true that most surgeons have stopped

placing the drains deeply in the cavity and are content to drain the wound down to the peritoneum. It seems clear that the deposition of more than 10 Gm of a sulfonamide is contraindicated inasmuch as the portal blood levels may rise as high as 60 mg per hundred cubic centimeters when greater quantities are given.

After operation the patient with peritonitis should be kept in Fowler's position. Every effort must be made to relieve distention which all too frequently is the precursor of fatal adynamic ileus. Change of posture gastric lavage duodenal drainage frequent enemas with turpentine use of stupes complete abstinence from food and fluids by mouth administration of chlorides intravenously and adequate rest at night all aid in the accomplishment of this result. Attempted stimulation of the paralyzed intestine by the use of drugs is futile. Operative procedures such as jejunostomy or ileostomy are contraindicated inasmuch as they fail to empty more than a few inches of intestine.

Prognosis—The prognosis in cases of acute appendicitis depends on the promptness with which the diagnosis is made and operation performed. Miles and his co-workers point out in their analysis of 910 cases of acute appendicitis that the mortality for a group of patients operated on in the first twenty-four hours of the disease was 2.7 per cent against a mortality of 6.5 per cent for patients in whom the duration of the illness was more than twenty-four hours. If the inflamed appendix is removed before perforation or gangrene has occurred the outlook for recovery is excellent. The deaths that occur following simple appendectomy without drainage of the peritoneal cavity are due to the anesthetic or to embolism and are exceedingly rare. The gravity of a case is increased a hundredfold if complicated by perforation or gangrene since either of these conditions can cause generalized peritonitis which inevitably results in death in a certain number of cases. When the infection reveals the peritoneum the prognosis is seriously altered for although there is walling off and localization of the infection death sometimes follows. Some observers think that operations performed just after natural walling off has occurred do more harm than good.

CHRONIC APPENDICITIS

It is unfortunate that this term has been used in medical circles for there has never been any agreement as to what constitutes the clinical picture resulting from so called chronic appendicitis and moreover there is no such pathologic entity. The term has been used loosely and often serves to mask the physician's ignorance of the real nature of a patient's ailment. One does see how ever changes in the vermiform appendix after an acute inflammatory process. These changes have been described in the preceding section and as pointed out they predispose to recurring infections. The term chronic recurring appendicitis is more in keeping with the facts and connotes the tendency to the recurrence of acute attacks. The pathologic alterations resulting from acute inflammation of the appendix may give rise to indefinite symptoms often referred to some other organ such as the stomach or intestines. Many times the patient is unable to describe the symptoms accurately or to give them an exact location. There may be anorexia, eructations, a sense of fullness after eating and tenderness in the epigastrium. In other cases the symptoms are referred to the lower abdomen. The patients complain of tenderness often diffuse but at times over the cecum. There may be borborygmus, constipation and indigestion. An aggravation of these symptoms is sometimes noticed after exercises such as bending, lifting or stretching. The indefiniteness of the syndrome makes the diagnosis uncertain but the history of an initial attack is suggestive. It is significant that appendectomy relieves the symptoms in only about half of the cases in which a diagnosis of chronic appendicitis is made.

WARFIELD M. FIRON

INTESTINAL OBSTRUCTION

GENERAL FEATURES OF INTESTINAL OBSTRUCTION

(Occlusion of the Bowel, Intestinal Stasis Ileus)

Definition.—In the broad sense any interference with progression of the intestinal current constitutes obstruction of the intestine. This conception embraces interference

with intestinal continuity from whatever cause and includes those of inhibitive (paralytic) as well as those of mechanical origin. In the more restricted interpretation of common usage however the term intestinal obstruction is often employed to denote obstructions of mechanical origin alone.

Etiology.—By far the larger number of instances of intestinal obstruction are caused by mechanical agents such as (1) narrowing of the lumen due to strictures of the intestinal wall, (2) obturation of its lumen by a foreign body or compression of the lumen from without, (3) adhesions, (4) hernia, (5) volvulus, (6) intussusception and (7) embryologic defects such as apertures in the mesentery, abnormal fixation as well as failure of rotation of the gut and Meckel's diverticulum. Upsets in the nervous mechanism interfere with intestinal motility; these may be inhibitive (paralytic) or spastic in nature. Finally interruption of the normal blood flow to or from the intestinal tract such as embolism or thrombosis of the mesenteric vessels or severance of vessels by trauma will effectually obstruct the onward motion of the intestinal content.

Strictures which obstruct the intestinal tract may be congenital or acquired, inflammatory or neoplastic. They may occur in either the large or the small intestine. Atresia of a segment of the small intestine and imperforation of the anal canal and rectum constitute the congenital stenoses which cause intestinal obstruction. Carcinoma in the sigmoid flexure of the colon and diverticulitis are the commonest instances of acquired stricture giving rise to occlusion of the bowel. In addition benign tumors such as lipomas, fibromas, polyps or hemangiomas and malignant tumors such as carcinomas, carcinoid tumors as well as sarcomas may occur in either the small or the large bowel and obstruct its continuity by encroachment on the lumen.

Obstruction of the intestine by compression from without is likely to occur only where the tract is fixed as in the pelvis or the retroperitoneal duodenum and less frequently in the terminal ileum.

Adhesions and hernia are generally the most frequently observed causes of intestinal obstruction. Oddly enough however geographic location seems to affect the in-

cidence considerably. In England, Australia and Denmark, intussusception constitutes one of the most frequently observed types of intestinal obstruction. Reports from Russia and Serbia indicate that volvulus is responsible for more than 50 per cent of all cases of obstruction observed, whereas, generally, it accounts for less than 10 per cent in most series.

As has been indicated, the main types of obstruction from the standpoint of causative factors are mechanical, nervous and vascular. A satisfactory classification for both clinician and pathologist may be made by correlating, with the commonly observed varieties of obstruction, the factors of etiology and pathologic appearance as indicated in the accompanying table (Table 13)

TABLE 13—COMBINED CLINICAL AND PATHOLOGIC CLASSIFICATION AND TREATMENT OF TYPES OF INTESTINAL OBSTRUCTION

Clinical classification	Pathologic classification	Treatment
I MECHANICAL OBSTRUCTION A Narrowing of lumen 1 Strictures of intestinal wall a Congenital { atresia imperforate anus inflammatory traumatic b Acquired { vascular neoplastic 2 Obturation 3 Compression from without (especially pelvis and retroperitoneal duode- num)	Simple (except in neoplastic strictures of the colon)	Operation preceded by suc- tion for decompression in late cases except in occlu- sion of the colon
B Intestinal obstruction due to adhesions and bands { congenital inflammatory traumatic neoplastic	Simple or strangulation	Suction operation for per- sistent obstruction and in strangulation
C Hernia 1 External 2 Internal D Volvulus E Intussusception F Developmental errors which give rise to in- testinal obstruction (other than congen- ital stenosis)	Strangulation	Early operation
II INTSTINAL OBSTRUCTION DUE TO NERVOUS IMBALANCE A Inhibition (paralytic) ileus B Spastic or dynamic obstruction	Simple	Suction
III VASCULAR OBSTRUCTION A Intestinal obstruction due to mesenteric thrombosis and embolism	Strangulation	Early operation

Pathologic Considerations.—*Classification*—From the point of view of a pathologic division, there are essentially two types of intestinal obstruction, viz., simple and *strangulating obstruction*. In the former are included all cases in which blockage of the continuity of the bowel exists, in *strangulation* there is in addition evidence of compromise of the blood supply.

Morbid Anatomy.—In simple obstruction the bowel above the obstructing mechanism is distended and in obstruction of an acute nature the wall is thinned out in chronic obstructions the intestinal wall is thickened largely as a result of hypertrophy of the circular muscle. The intestine in acute obstruction is as a rule somewhat redder than usual owing to hyperemia of its wall. The distention is due to the accumulation of fluid and gas proximal to the obstruction. The length of the intestine concerned in the distention is dependent on the duration of the obstruction. The

degree of distention is determined largely by whether the obstruction is partial or complete. High grade distention usually accompanies total occlusion occasionally the intestinal wall weeps and a serous fluid may be present in the peritoneal cavity. The intestine distal to the obstruction is usually empty and contracted. The only commonly observed obstruction of a simple nature which frequently exhibits the pathologic features of strangulation is a stricture of the colon the reason for which will be discussed presently.

Though there is a possibility for serous interference with the flow of blood through the agency of increase in intraluminal tension actually the anatomical effects of such an influence are apparent only in the obstruction of closed loops. These may be established experimentally by inverting both ends of a segment of intestine clinically they must be observed in cases of obstruction of the colon in which the competent proximal ileocolic sphincter makes this simple obstruction a virtual closed loop in which the effects of a markedly increased intraluminal tension become evident ulceration gangrene and perforation.

Direct measurements of the tension within the bowel have been made by the writer at operation. Despite enormous distention of the small intestine, pressures of the order of magnitude of from 4 to 16 cm. of water have been recorded. The participation of long segments of bowel in the distention precludes the occurrence of a high sustained pressure. In colonic obstruction however great increase of the intraluminal tension is usually found pressures of from 20 to 30 cm. of water having been observed.

All the signs of tissue death may be observed in the intestinal wall in obstruction of a strangulating character. The wall varies in color from that of a dusky cyanosis to a bluish black. This discoloration is occasioned by hemorrhagic infarction of the wall consequent on arrest of return of the venous blood from the intestine. In addition the lumen may be filled with blood and there is often a serosanguineous transudate in the peritoneal cavity. The loss of blood may be great when the strangulated segment is long. The arrest of the flow of blood concerns largely prevention of egress of blood from the bowel since blood continues to be pumped into the intestine under the motive force of systolic blood pressure leaks in the veins occur and considerable blood may be lost. When the intraluminal tension becomes great enough to compress the capillary circulation of the intestine anemic necrosis and gangrene or perforation may occur.

The return of normal color to the bowel wall and contractile responses on pinching it together with normal pulsations in the mesenteric vessels determine after the intestine has been released from the strangulating mechanism whether the intestine is still viable.

The bowel above the strangulated segment exhibits the various changes previously described under simple obstruction.

Physiologic Considerations—Hartwell and Hoguet found that dogs that were given saline solution subcutaneously survived for a considerable time obstruction of the upper intestine which otherwise proved fatal in a few days. This finding has been corroborated by a number of experimental workers in the field. It was first believed that the saline solution detoxified

a toxin X and acted as an antidote for the poison absorbed. It was later demonstrated that after temporary administration the saline solution could be discontinued and the dogs lived about as long. After having been temporarily fortified in this manner against loss of fluid from the upper reaches of the alimentary canal by vomiting the dogs apparently accommodated themselves to this dehydration process.

High intestinal obstruction or complete duodenal fistula (in which fluids are similarly lost) in dogs causes the development of characteristic changes in the chemistry of the blood: decrease of the chlorides increase in the alkali reserve and elevation of the non protein nitrogen content. If saline solution is administered these changes do not occur.

If the obstruction is located in the lower portion of the ileum or in the colon these changes are rarely observed probably because the electrolytes largely sodium and chloride ions which are seriously depleted in obstruction of the upper bowel are afforded an opportunity for at least partial absorption in low obstructions. The administration of saline solution to dogs with ileal and colonic obstruction does not prolong their lives as it does in high jejunal obstructions. Saline solution exhibits the virtues of a specific in these high occlusions therefore because it serves as an adequate substitute for the fluids lost by vomiting. Other fluids or different combinations of sodium and chloride radicals will not ward off early death in such animals.

There are three possible sources of the gas in the distended bowel. By far the greater portion is (1) swallowed air (70 per cent) the remainder is to be accounted for as a result of (2) local putrefaction and fermentation and (3) a portion is brought to the bowel by an interchange from the blood stream. Since the swallowed air is largely nitrogen (80 per cent), it is not readily absorbed. Carbon dioxide which largely results from fermentation is readily absorbed under ordinary conditions but not when the bowel is distended. Ammonia methane hydrogen and hydrogen sulfide products of putrefaction are not readily absorbed.

The fluid component of the distention comes largely from the digestive secretions. Under conditions of obstruction however the secretion from the intestine itself seems to be enhanced an irritative phenomenon as a result of the dilatation of the bowel wall apparently and in part due to the increased osmotic pressure of the bowel fluids occasioned by lack of normal absorption.

The cause of death in strangulation obstruction in which the loss of blood may be great and death of tissue occurs is not difficult of interpretation. In simple obstruction on the contrary apart from the high obstructions which have just been described and which incidentally are rarely observed clinically the cause of death is still unknown.

It has been predicated that an abnormal toxin not unlike histamine forms in the bowel the absorption of which brings on the sequence of consequences which lead to a lethal issue. The injection of fairly large quantities of histamine into such a segment however appears to be well borne.

Continued distention of long segments of bowel which cannot be emptied adequately by vomiting results in sustained increases of intraluminal tension and

occurrence which opens up a new avenue of absorption viz transperitoneal migration of noxious toxins and bacteria, through the injured bowel wall. Without question this is the most serious consequence attending unrelieved simple obstruction. Increased intraluminal tension interferes with venous outflow from the bowel wall. Increases in venous pressures are reflected directly by similar increases in capillary hydrostatic pressure. In consequence there is increased capillary filtration with increased edema of the bowel wall which owing to increasing distention is at the same time becoming thinner also. Anoxia of the bowel wall with impaired vascularity and increased capillary permeability is a natural result.

Intestinal distention may be attended by increases in the venous pressure in the lower extremities and by slowing of the circulation time as determined by the sodium cyanide method (Bell's and Wangersteen 1939). That loss of blood is an important item in strangulating obstructions was pointed out by Scott and Wangersteen in 1939. This observation has been confirmed by a number of investigators. Fine and his associates have described diminution in plasma volume in simple obstruction (1940).

Symptoms—The chief complaints of patients with intestinal obstruction are of pain and vomiting and later when the obstruction has become well established distention. The pain is intermittent and crampy and is usually described by the patient as a gas pain. The cramp is usually not long in duration; it rises in crescendo fashion and quickly reaches its peak and after being sustained in its maximum severity for a variable length of time usually one to three minutes abruptly ceases. A plateau type of pain curve is practically never observed. Occasionally, as noted not infrequently in intussusception, the pain may be somewhat rhythmic in its occurrence. This colicky distress may recur frequently or at long intervals depending on the nature of the obstruction. Late in the course of obstruction when the intestine has become considerably dilated and the optimal contractile diameter of the intestine has been exceeded the colic is less severe.

Whereas reflex vomiting may occur in any acute abdominal disorder the significance of mechanical block in determining the character of the vomitus becomes apparent in intestinal occlusion. When high grade occlusion of the small intestine occurs incident to the accumulation of fluid and gas above the site of obstruction the vomiting is frequent and copious. There is only one variety of obstruction of the bowel in which the distention may be great and yet no vomiting

occurs viz obstruction of the colon. The rapidly formed distention apart from the reflex vomiting which may occur initially has no bearing on this peculiarity. This circumstance attests only the importance of the regurgitant feature in the vomiting of bowel occlusion. In obstruction of the colon the proximal ileocolic valve and sphincter are usually competent and behave like a check valve permitting gas and fluid to come into the colon from the ileum without regurgitation into the ileum. In this the usual situation the distention remains limited to the colon and the small intestine does not participate in it frequently despite enormous distention there may be no vomiting.

Physical Findings—General—The appearance of the patient early in the course of obstruction often affords no evidence that he is suffering from a potentially serious ailment. The pulse rate, respirations, temperature and blood pressure are usually normal. Apart from the pain of which he complains the vomiting and the distention he may not appear to be particularly ill. Late in obstruction owing to dehydration and other changes in bodily economy not wholly understood an anxious expression with sunken features, a feeble pulse and cold and livid extremities are noted.

In strangulating obstructions especially if the segment is long to which the blood supply is compromised the pulse may be hurried if the blood loss is great the symptoms of shock may be present. Owing to the irritation of the parietal peritoneum by the sanguineous fluid which escapes into the peritoneal cavity the patient suffers more distress than the patient with simple obstruction.

Abdominal Findings—When the patient is first seen there is usually moderate distention. In a chronic obstruction visible peristalsis is almost invariably present; the outline of the intestine may be observed on the abdominal wall and the peristaltic rushes felt with the hand. In an acute obstruction of short duration however peristalsis is not visible unless the abdominal wall is abnormally thin. Visible peristalsis is synonymous with hypertrophy of the circular muscle of the intestine and necessitates the elapsing of perhaps at least a week for its develop-

ment The diaphragmatic component of respiration is not ablated as often occurs in perforation of the upper reaches of the intestinal canal In simple obstruction the abdominal wall usually remains soft and no evidence of tenderness or rigidity of the abdominal muscles is present Occasionally but not often during the acme of the pain there may be slight tightening of the abdominal muscles which relax completely again when the pain is gone In strangulating obstruction on the contrary blood or hemorrhagic fluid escapes into the peritoneal cavity and gives rise to peritoneal irritation* If an infarcted segment of intestine is present it may be felt as a mass through the abdominal wall or by digital examination of the rectum and vagina In simple obstruction when the distention is great in consequence of which the intestine may weep slight rebound tenderness may be present The degree of rigidity of the abdominal muscles however rarely becomes great If considerable fluid escapes into the peritoneum there may be pain in the shoulder due to irritation of the diaphragmatic peritoneum If the distention is great tympany will be marked Were it not for the gas in the intestine and the air in the lungs both would be as dull as the liver on percussion

The most significant findings are obtained on auscultation If a patient suffers from a block in the intestinal continuity borborygmi may be heard at the height of the intermittent pain of which he complains The concomitant occurrence of borborygmi at the acme of the pain establishes the presence of *intestinal colic* It then only remains to be determined whether the *intestinal colic* is that of bowel obstruction food indiscretion allergy or enterocolitis These intestinal sounds are usually gurgling bubbling noises much like those produced by pouring water out of an inverted bottle with a narrow neck

* The parietal peritoneum is the most sensitive of all the serous membranes The degree of peritoneal irritation present is usually predicated on the character of the irritant The most pronounced rigidity of the abdomen is observed attending the perforation of a duodenal or gastric ulcer into the free peritoneal cavity with escape of hydrochloric acid pancreatic juice and bile Perforation of the rectum may be accompanied by abdominal pain which is scarcely appreciable for feces through a source of danger to the peritoneum, is not a severe irritant.

If the bowel is under considerable tension the noise has a metallic character Whereas such sounds may be heard with the stethoscope over the abdomen under a number of varying circumstances unless the noises are due to *intestinal colic* there is no intimate time relationship between pain and borborygmi

Laboratory Data—General—In consequence of the dehydration concentration of the blood occurs and increased values for hemoglobin red cells and leukocytes may be obtained Rebound abdominal tenderness associated with a mounting leukocyte count frequently portends the presence of a strangulating obstruction The urine is usually scant and albumin or casts may be present The urinary function is not impaired however for the liberal administration of saline solution corrects the oliguria and the abnormal findings disappear

The alterations in the blood chemistry previously described under Physiologic Considerations are of no diagnostic value in determining the presence of intestinal obstruction except in atypical instances Decrease in the blood chlorides increased combing power of the blood for carbon dioxide and elevation of the non protein nitrogen content are observed with regularity only in high obstructions and then only after forty-eight hours

Röntgen Examination—Valuable evidence is obtained by roentgen examination in the diagnosis of intestinal obstruction Only rarely is the administration of an opaque medium permissible A single large scout film of the abdomen taken with the patient lying supine indicates the degree of intestinal distention present and determines where the distended coils are located A film taken with the patient sitting or erect shows gas mirrored over fluid but the configuration of the distended coils and the degree of distention are not apparent The scout film is consequently far more informative The exact location of the probable site of obstruction is determined by the distended intestinal loops is not as accurate for the small intestine as for the colon On the whole however it may usually be said whether the distention concerns the upper middle or lower third of the small intestine Gas is present throughout the gastrointestinal

canal, but normally in the adult it is visualized on the roentgen film only in the stomach and colon. In infants and children until about three years of age, gas may be seen throughout the intestine. The rapidity of transit through the small intestine is such that gas and fluid are so intimately intermixed as to preclude their demonstration on a roentgenogram. In the stomach and colon, where food and intestinal content remain for considerably longer periods, gas and fluid separate out. If intestinal stasis occurs in the small intestine from any cause, fluid and gas separate, and gas may be visualized on the roentgen film.

Fig 558—Enormous distention of the small intestine in a patient with intestinal colic. There was no gas in the colon, and no rebound tenderness. Therefore there was a complete simple obstruction of the lower ileum. (Enterostomy was performed; the patient has had no obstructive symptoms in the eleven years since then.)

It is immediately apparent that the roentgen findings must be correlated with the clinical observations. Whether the stasis is mechanical or inhibitive (paralytic) in origin, one may not be able to tell from an inspection of the roentgen films alone. To be certain, usually in inhibitive (paralytic) ileus, the entire intestinal tract is distended, whereas, in mechanical obstructions the distention concerns only the portion above the site of the occlusion even though there may be some gas in the colon beyond the obstruction. The stethoscope gives a dependable verdict.

Is the Obstruction Complete or Incomplete?—The chief source of gas in the intes-

tine is swallowed air. In mechanical obstructions it is a good plan to administer a soap and water enema which is expelled prior to taking the roentgenogram. If the gas persists in the colon after this it is probable that it has leaked past the obstructive mechanism and that the obstruction is incomplete. Absence of gas in the colon on such a film after evacuation of the colon by enemas indicates that the obstruction is complete (Fig. 558). When the presence of an inflammatory lesion in the peritoneal cavity is suspected and, particularly when appendicitis is a diagnostic possibility, the administration of an enema, either for pur-

Fig 559—Gaseous distention limited to the colon in a patient with intestinal colic. There had been no vomiting or gastric retention. There was an annular carcinoma in the sigmoid flexure of the pelvic colon.

poses of diagnosis or in the attempt to secure expulsion of gas, is contraindicated.

Factors Contributing to Delay in Diagnosis of Obstruction.—*Absence of Local Physical Findings.*—Lack of appreciation of the fact that simple obstruction of the bowel does not give rise to local physical findings, viz., tenderness and rigidity, often results in the impression that only a trivial condition is present. When it is remembered, however, that simple obstruction of the bowel is the only serious acute lesion which does not give rise to abdominal tenderness, a lack of local physical findings in a patient with abdominal pain, nausea and vomiting should make one suspicious of the presence of intestinal obstruction.

Mistrust in Enemas—It is frequently said that total obstipation characterizes intestinal obstruction. The bowel distal to the point of obstruction is physiologically as well as anatomically normal. In incomplete obstruction therefore gas may continue to be evacuated as long as enemas are administered. Only in complete low obstruction is total obstipation certain. The expulsion of gas and feces with an administered enema does not militate against the presence of obstruction.

Abuse of Morphine—The administration of morphine before the diagnosis is established assures the pain and lulls both patient and physician into a sense of false security. *Intestinal colic*, the pathognomonic sign of intestinal obstruction is abolished. Morphine does not paralyze intestinal contractions; on the contrary it enhances the tone of the normal as well as the obstructed portion of the tract. The significance of the intestinal borborygmi which are to be heard on auscultation of the abdomen cannot be properly evaluated when pain is abated.

Deception of Apparently Effectual Cathartics in Partial Obstructions—The expulsion of a stool after the administration of a cathartic does not mean that the bowel is not obstructed and continuance of the pain indicates that the obstruction is still present. The employment of cathartics in mechanical obstruction is not to be recommended like morphine they are a dangerous expedient.

Differential Diagnosis—The first essential in the diagnosis of obstruction is to establish the absence or presence of *intestinal colic*. Occlusion of the bowel is not caused by conditions which fail to produce it. In simple obstruction in which local physical findings are absent enterocolitis, dietary indiscretions and allergy must be excluded. On the basis of the history of the complaint the presence or absence of diarrhea and the nature of the constitutional symptoms the differential diagnosis is usually readily made.

In strangulating obstructions accompanied by abdominal tenderness and rigidity a large number of possibilities must be excluded. Here too the absence or presence of *intestinal colic* is the chief determinant. Occasionally in lesions such as strangulation of an ovarian cyst, a ruptured appendix or pelvic

inflammation obstruction of the intestinal tract by the mass exudate or fibrinous adhesions may concomitantly obstruct the bowel and give rise to *intestinal colic*. In such instances at times it may be difficult or impossible to determine whether strangulating obstruction with the formation of a mass and the development of tenderness and rigidity of the abdominal wall was the primary condition or whether a simple obstruction was superimposed on one of the aforementioned conditions.

Identification of the Type of Obstruction Present—The exact nature of an obstruction is an item concerning which information is largely inferential and not absolute. External hernias, the congenital obstructions such as intestinal atresias and imperforations of the rectum and anal canal and intussusception of infancy may usually be accurately identified by the rather obvious findings or characteristic train of symptoms. Obstruction of the colon is due usually to carcinoma and less frequently to diverticulitis. Spastic functional obstruction of the colon can usually be recognized by the occurrence of findings to be described under that caption. The greatest difficulty is the determination of the exact nature of an obstruction in the small intestine. When external hernia and intussusception which statistically are rather common types of obstruction are excluded adhesive obstruction is by all odds the most likely. Yet obstruction of the small bowel by a gallstone, carcinoma or an enteric intussusception though uncommon occurs sufficiently frequently to demand attention in the consideration of the probable nature of an obstruction of the small intestine.

Prognosis—Whereas the mortality in acute intestinal obstruction has been unacceptably high (40 to 60 per cent) the more general early recognition and the employment of more rational procedures have resulted in definite improvement. In such obstructions as congenital atresia, strangulating obstruction, inhibitive (paralytic) ileus due to peritonitis and mesenteric thrombosis the risk will always be great because of the obvious seriousness of these conditions. Early diagnosis and the judicious choice of well executed therapeutic procedures should be accompanied by a low mortality in most

types of obstruction. Though there are a number of potential strangulating obstructions, the time element figures prominently in all of them. The single variety of obstruction in which the blood supply is actually not available to the bowel is embolism or thrombosis of the mesenteric vessels. Release of the constricting agent in all other strangulating obstructions before the anat-

mechanical obstruction submitted to operation, the procedure of election may be carried out, viz., finding and determining the exact nature of the obstruction followed by accomplishment of its release. In late simple obstructions, release of the obstruction may be associated with an unnecessary hazard, and experience has shown that mere decompression of the intestine is safer. When

mic changes consequent on prolonged interference with the blood supply of the segment have occurred obviates the necessity of dealing with a non-viable bowel. This is one of the most fundamental considerations in the treatment of all intestinal obstructions.

Treatment.—The ideal objective in mechanical occlusion is release or removal of the obstructing agent. In instances of early

the blood supply of the intestine is compromised by strangulation, freeing the gut of the obstructive mechanism is invariably mandatory, no matter how ill the patient may be.

In general it may be said that the agents of demonstrated value in the relief of ob-

struction are (1) eradication of the obstructing mechanism by operation (2) decompression of the distended intestine (enterostomy or colostomy) or circumventing the obstruction by enteronastomosis, (3) decompression of the distended intestine by suction applied to an intubing duodenal tube (4) administration of saline solution and (5) blood and plasma transfusions

In parietic conditions of the intestinal tract agents such as hypertonic saline solution administered intravenously (Hughson and Scirff 1924) spinal anesthesia and drugs which enhance the contractile activity of the bowel (Ochsner, Gage and Cutting 1930) as well as enemas have a place. On the whole, however, their effect is transient, and decompression by suction applied to tubes introduced into the upper and the lower reaches of the intestinal tract constitutes a far more rational attack on the distention.

Operation—There are essentially two types of operative procedure employed in the treatment of intestinal obstruction. 1. A direct attack is made on the obstructive mechanism with establishment of the intestinal continuity. Occasionally this may be achieved by the release of an adhesive band, sometimes it necessitates the excision of a segment of the intestine (intestinal resection) together with the obstructing agent. This may be done in one stage (primary resection) or in two stages in which exteriorization of the offending segment is first done followed by subsequent anastomosis of the exteriorized loops of intestine by suture. Now and then it may appear wiser to make an initial enteronastomosis around the obstructing agent to be followed later by its excision. 2. The indirect attack consists in merely establishing an external vent for drainage of the distended intestine in any segment of dilated intestine proximal to the point of obstruction. In obstruction of

the small bowel in accord with laws of good plumbing the drainage (enterostomy) should be fairly close to the point of obstruction in the colon the site of establishment of the external vent (colostomy) may depend on whether one wishes total or incomplete deviation of the fecal stream as well as on whether a subsequent operative attack may make it desirable to place the opening rather remotely from the site of the obstruction. Incomplete deviation of the fecal current in the colon may be achieved by appendicostomy, cecostomy or simple drainage through a tube. Complete deviation is to be achieved only by bringing a segment of the colon up on the abdominal wall.

In the performance of enterostomy or colostomy, it is essential that there be absolutely no spillage. An aseptic drainage must be established. Whereas in the unobstructed bowel slight contamination or soiling is usually inconsequential the occurrence of the most minute spillage in drainage of the obstructed intestine because of the multiplication of bacteria is synonymous with death from peritonitis. In addition to the establishment of aseptic drainage of the intestine it is important in obstructions of the small bowel to perform the enterostomy in such a manner that the vent will spontaneously close when the tube comes away (Fig. 560).

Determination of the Viability of the Intestine—If the bowel has a purplish discoloration it is immediately apparent that it is strangulated. If after release of the constriction the normal color returns to the bowel and pulsation to its vessels and the wall contracts on mechanical stimulation the bowel is viable, if the wall remains discolored after it has been left in a warm saline pack for a few minutes it is devitalized and should be excised. Under ordinary circumstances it is safer to establish the intestinal continuity after initial exteriorization of the

break the suction if the intestinal mucosa exhibits a tendency to cling to the perforations in the tube. The trochar accommodates a no. 20 F long rectal tube. segment than by primary resection. All anastomotic operations in the presence of intestinal obstruction carry a high risk for the patient.

Decompression by Suction Siphonage Through Inlying Duodenal Catheter—Most instances of incomplete simple mechanical obstruction of the small intestine may be safely treated by suction applied to an inlying duodenal tube. Similarly lesser grades of colonic obstruction may be decompressed by aspirating the gas and fluid at the gateway of the intestinal canal which contribute largely to an augmentation of the distention. Experience indicates that a number of instances of mechanical obstruction of adhesive origin may be satisfactorily treated by this means without operative intervention. Just as enterostomy usually permits automatic establishment of the continuity of the intestine after drainage, so decompression by suction applied to a duodenal tube frequently accomplishes an adequate release from the obstructing mechanism. The advantage which enterostomy presents over suction applied to a duodenal catheter is that the bowel above the site of enterostomy may be used as a nutritive tube until the continuity of the tract is established. The Miller Abbott balloon tipped tube which may, after entry into the duodenum, pass readily down the distended intestine has increased somewhat the likelihood of decompression in suitable cases through the agency of an indwelling tube. Subsequent operation for removal of the adhesive constricting agent is usually not necessary whether the decompression is achieved by means of enterostomy or by the duodenal tube. Should subsequent seizures of *intestinal colic* recur, however, an operative attack on the offending agent should be performed.

In inhibitive (paralytic) types of ileus suction applied to an inlying duodenal as well as rectal tube is of great value. Of course the prophylactic prevention of distention on the whole is more efficacious than treatment of established distention. When distention is to be anticipated following certain types of abdominal surgery, as operations on the biliary ducts and the stomach, the early employment of suction is of greatest value in obviating the occurrence of distention.

Contraindications—Attempts at obtaining decompression by this means are not to be attempted in strangulating obstructions or in acute obstructions of the colon with enormous distention in which the ileocolic valve and sphincter limit the distention to the large intestine. Operative intervention is indicated in such instances.

Limitations of Conservative Decompression—It is the interspersion of segments containing collections of gas and fluid that renders suction ineffectual. If the entire stomach and small intestine were distended with either fluid or gas alone, the exertion of 75 cm. of water suction (about the optimal degree of negative pressure) applied to a duodenal tube engaged in the upper reaches of the bowel would immediately empty out the entire intestinal canal and this grade of negative pressure would be appreciated in almost the same degree at the cecum. With the possibility of doing away with the accretion of distention by continuous aspiration of swallowed air and constant removal of the fluids from the upper reaches of the intestine as they enter the intestinal canal from the stomach, liver and pancreas, with the confluence of gaseous and of fluid increments owing to changes in posture of the patient, the contractions of the intestine and absorption of fluid from the bowel, the existing distention is favorably influenced. The use of the Miller Abbott type of duodenal tube with an inflatable balloon at the tip has set aside some of these difficulties. For once this tube has entered the duodenum its transit down the bowel is usually fairly rapid.

In cases of mechanical obstruction it is necessary to follow the decompression with roentgenograms every twelve or twenty-four hours to note whether the caliber of the distended intestine is becoming smaller, because usually the pain stops when suction is commenced, also the bowel accommodates itself to a certain grade of distention and ceases to cause painful contractions if the existing distention is not augmented.

Rectal suction for colonic decompression because of the presence of feces is not as efficacious as suction applied through an inlying duodenal tube. Irrigation alternated with suction proves more satisfactory (tidal irrigation).

Saline Solution and Fluid Administration

—The greatest value of saline solution lies in its power to combat dehydration. Most clinical obstructions are low in the physiologic sense hence no specific virtue is to be expected of saline solution such as may be observed in experimental high obstruction or in a patient who has in obstruction at the

intelligent orientation concerning the salt requirements. Similarly, a careful hemoglobin determination together with ascertainment of the specific gravity of the plasma will indicate the degree of hemoconcentration or of dehydration that may be present.

Enough fluid should be given to maintain

Fig. 56²—Diagram of suction apparatus employed in the treatment of intestinal obstruction. An effort should always be made to have the end of the catheter reach beyond the duodenum. Perforations are made so that suction may be exerted simultaneously on the stomach and on the duodenum. When the fluid aspirations are great a third bottle should be used as a collecting receptacle.

stoma after gastrojejunostomy or gastric resection.

In instances in which vomiting has been profuse one may expect reasonably that dehydration and dechlorination will have to be treated. Coller and his associates (1938) have formulated practical rules for the administration of salt and fluid under such circumstances. Plasma chloride determinations should be made as a matter of routine for

daily urinary output of 700 to 1000 cc per twenty-four hours. Daily determination of the sodium chloride excretion in the urine together with periodic determination of the plasma chlorides will suffice to indicate the daily requirements of sodium chloride that must be met.

In addition to meeting the fluid electrolyte and vitamin (especially B and C)

* Wargenstein and Lane JAMA 110

requirements it is becoming increasingly evident that maintenance of caloric and nitrogen equilibrium in surgical patients is of the greatest importance. In patients with obstruction of the gastric outlet or intestinal canal the caloric and nitrogen balance can be maintained by intravenous feeding alone for short periods of time (two to three weeks). The slow intravenous infusion of 20 per cent glucose solution through a 22 gauge needle in the forearm or leg allows the administration of about 300 Gm (1500 cc of 20 per cent solution) over a ten to

red pulse with other signs of impending or actual shock. Instances of volvulus intussusception strangulated hernias and torsion of the intestine due to adhesions represent instances in which the possibility of a serious loss of blood may be great. In all such instances adequate replacement of the loss by transfusion should be carried out before operation is undertaken. More and more the value of plasma in treating blood loss as well as blood volume reductions through loss of plasma is being universally recognized.

Fig. 563—Incidence of various types of obstruction in a ten year period at the Massachusetts General Hospital during which time there were 32,936 surgical admissions. In the writer's experience adhesions constitute the most frequent cause of obstruction.

twelve hour period without great inconvenience to the patient and without much spillage of sugar in the urine. Daily quantitative determinations of the sugar lost in the urine are important to determine and regulate the rate of infusion. Amino acids and a complete protein such as plasma will sustain the nitrogen equilibrium on intravenous injection.

Transfusion—In all cases of strangulating obstruction there is some loss of blood into the infarcted tract. If the segment is long loss may be great as is indicated in a hur-

Oxygen—Inhalation of high concentrations of oxygen (Fine and his associates 1936) may facilitate diminution of intestinal distention by lowering the nitrogen tension in the plasma thus encouraging the slowly diffusible nitrogen in the lumen of the bowel to be given up for excretion through the lungs. There appears to be some hazard, however if high concentrations of oxygen in excess of 80 per cent are given over long periods of time without interruption (J. R. Payne 1941).

BRIEF CONSIDERATION OF THE VARIOUS TYPES OF INTESTINAL OBSTRUCTION

I MECHANICAL OBSTRUCTION

A NARROWING OF THE LUMEN

1 STRICTURE OF BOWEL WALL

a Congenital Atresia (see section on Congenital Atresia)

b Imperforate Anal Canal and Rectum
—*Etiology*—Atresia of the anal canal or of the lower portion of the rectum occurs once in about every five thousand births. The division between the sexes is about equal. Not infrequently it is attended by the presence of other embryological defects.

Embryological Anatomy—Failure of the anal plug to break down brings about the condition of imperforate anus. Incomplete migration of the hind gut atresia of the rectum. The malformation in imperforate anus concerns almost solely the postallantone gut, that is the portion of the hind gut caudal to the allantois that grows down and joins the anal plate. The abnormal development of imperforation therefore concerns only this segment of the gut and does not extend higher than the inferior portion of the primitive cloaca.

Pathology—Two types of imperforation are recognized viz., with or without abnormal fistulous communication of the terminal bowel. Sueda's classification on this basis is widely accepted. Of 114 cases of imperforation collected by Ziemendorf (1909) these divided themselves as follows with reference to Sueda's table:

Type I	Cases	Per cent
1 Anal atresia	28	24.6
2 Rectal atresia	16	14
3 Anal and rectal atresia	8	7
Total	52	45.6

Type II	Cases	Per cent
1 Vaginal fistula	39	33.3
2 Urethral fistula	11	9.6
3 Vesical fistula	9	7.9
4 External fistula	4	3.5
Total	62	54.3

The nature of the occlusion in imperforation may vary from a thin diaphragm to imperviousness of the entire length of the anal canal and rectum. Stenosis without actual atresia may also occur. Owing to the early segregation of the urinary and genital passages in the female vesical and urethral terminations of the rectum are unknown in that sex. The almost invariable site of termination of the fistulous tract is in the posterior commissure of the vagina. In the male communication with the prostatic urethra is usually established by a narrow tract when the communication is without the bladder the termination may be cloacal in type.

Clinical Features—In hospitals the occurrence of atresia is usually established when

an attempt is made to secure the baby's temperature with a rectal thermometer. In anal atresia casual inspection of the perineum serves to identify the nature of the lesion. When routine examination of the newborn is not regularly made, the presence of imperforation may escape detection until failure to evacuate meconium is noted. Vomiting and intestinal distention occur in most instances.

The degree or extent of the impervious or atresic bowel cannot be made out by the ordinary criteria of physical examination. If the infant is held in the inverted posture however the height to which the gas ascends

Fig. 561—Manner of determining the degree of imperfection present and the order of magnitude of the surgical approach necessary to tap the distended gut. In the inverted posture gas mounts as high as the obstruction extends.*

in the pelvic colon and rectum as indicated in a roentgenogram serves to determine the extent of the imperforation (Fig. 564).

Prognosis—In occlusion of the anal canal or rectum without fistulous communication prolonged survival without the establishment of an external opening is impossible. Infants with vaginal termination of the rectum may frequently be seen because of an abdominal mass occasioned by the accumulation of feces above a narrow outlet. In the male fistulous termination in the urinary tract usually eventuates in pyelonephritis.

*Wangensteen and Rice. Ann. Surg. 90. J. B. Lippincott Co.

unless the communication is obliterated and an external opening is established for the escape of feces

Treatment—The early establishment of an avenue for the escape of gas and feces is indicated. Almost invariably this is best accomplished by means of a perineal incision (proctoplasty). A roentgenogram taken with the infant inverted indicates the depth at which the bowel will be reached. Recourse to colostomy is rarely necessary and should be avoided because of the increased risk. In vaginal termination of the rectum simple daily dilation of the narrow tract followed by its implantation through the fibers of the external sphincter in later childhood is indicated. The risk of the operative relief depends largely on the order of magnitude of the procedure found necessary to establish an outlet for the escape of feces

c. Acquired Strictures—Etiology—Stenosis of the bowel brought on by acquired strictures may be due to (1) inflammatory (2) neoplastic or (3) traumatic causes. Of these the third is the most infrequent and may be said to be a rare occurrence. Occlusion due to the formation of a stricture has been reported after blunt trauma to the abdominal wall. The usual circumstance in such instances is severance of the mesentery to a short segment of the intestine which accident is survived. Subsequently cicatrization of the intestinal wall occurs and stenosis supervenes. The more frequent occurrence is traumatic stricture after incarceration or strangulation of the intestine in a hernia particularly in the femoral canal.

The formation of a stricture may attend any ulcerative process in the bowel but is observed most commonly in intestinal tuberculosis. A tuberculous ulcer which has its axis transverse to that of the intestinal tract and which is usually exhibiting signs of healing gives rise to stricture that results in intestinal obstruction. These are frequently multiple. Hyperplastic tuberculosis an isolated type which has a predilection for the cecum may give rise to obstruction. Syphilitic strictures of the bowel have been known to give rise to obstruction. Similarly following on the ulceration of the bowel attending bacillary dysentery and typhoid fever strictures causing intestinal obstruction have

been observed. The ulceration in typhoid is in the axis of the bowel and the formation of a stricture is rare. Inflammation in diverticula (diverticulitis), commonly observed in the pelvic colon of persons past middle life rather commonly gives rise to large masses which obstruct the colon. Because of the not infrequent concomitant occurrence of carcinoma in this location of the colon an accurate differentiation is possible only by means of microscopic examination.

Obstruction due to a neoplastic process may be occasioned by either a benign or a malignant tumor. Benign tumors occur more frequently in the small intestine and the malignant in the colon with the exception of sarcomas which occur more frequently in the small intestine. Of the benign tumors lipoma myoma fibroma adenoma and angioma are the more usual offenders. All of these except adenoma show a predilection for the small intestine. An enterocystoma of congenital origin not infrequently associated with a persistent Meckel's diverticulum occasionally gives rise to intestinal obstruction. Gaseous cysts of the intestinal wall have been known to cause obstruction of the bowel.

Pathology—The majority of these lesions give rise to a simple obstruction of the bowel. Benign tumors of the small intestine and large bulky adenomas or carcinomas of the colon occasionally bring about occlusion by intussusception. The carcinoma tumors which occur in the small bowel have given rise to obstruction in about 10 per cent of the reported instances. These are to be differentiated from carcinoma of the small intestine by their reaction to the silver stain. Both give rise to metastases. Carcinoma as well as carcinoma tumors of the small intestine is usually single but may be multiple.

Carcinoma of the colon is a frequently observed cause of obstruction in older persons. Obstruction of the left half of the colon where the intestinal content first begins to assume solid form occurs eight times more often than in the proximal half. The sigmoid flexure with the narrowest lumen of any portion of the large bowel, is most frequently the site of obstruction in the colon. The anatomical arrangement of the flexures particularly the splenic flexure predisposes to obstruction. When obstruction occurs as a result of a cecal carcinoma it is the small bowel that is obstructed.

Nine of every 10 cases of mechanical obstruction of the colon are due to carcinoma. About 40 per cent of the patients with carcinoma of the large bowel who present themselves for treatment come because of chronic or acute intestinal obstruction. Acute obstruction is most frequently observed in the annular sigmoid carcinoma in the sigmoid flexure.

Owing to the usual competence of the ileocecal sphincter an obstruction of the colon when attended by considerable distention tends to become strangulating in character. The ileocecal sphincter and valve usually behave like a check valve permitting fluid and gas to be forced into the colon but there is no escape of the contents of the distended colon back into the small intestine. At operation despite enormous distention of the entire colon the last few inches of the ileum are usually found to be not distended. The cecum has the largest diameter of the colon consequently it dilates most readily and usually shows the greatest effects of increased intraluminal distention (Fig. 539). Ulceration, hemorrhage and perforation observed most frequently in the cecum occasionally attend this type of obstruction when it remains unrelieved for some time.

Symptoms—A stricture of the small bowel whether due to a neoplastic process, inflammation or trauma usually gives rise to subacute attacks of intestinal colic. When the patient presents himself with intestinal obstruction *variable peristalsis* is often in evidence and loops of small intestine may be felt and seen through the abdominal parietes. The patient may have relatively long intervals of freedom from attacks. In most instances of obstruction of the small bowel through carcinoma progressive loss of weight and occasional attacks of pain and vomiting are usual. The finding of occult blood in the stool lends confirmation to this impression particularly if the stomach and colon are known to be free from disease. Because of the fluid character of the content of the small intestine narrowing of the lumen by the stenotic process must be considerable before obstruction becomes persistent. Such patients have come under the writer's observation with a story suggestive of intestinal colic but on examination no objective demonstration could be made of the existence of a block to the bowel by clinical or roentgen evidence.

In obstructions of the colon due to strictures which are largely neoplastic in character vomiting is frequently absent despite the presence of enormous distention. This occurrence is readily accounted for in the lack of participation of the small intestine in the distention. When the lips and usually the lower lip of the ileocecal valve are deficient regurgitation into the terminal ileum may attend colonic obstruction. When a duodenal tube is passed into the stomach no retention may be found. Antecedent attacks

of abdominal pain associated with temporary meteorism are frequent, a history of constipation extending back over some period of time is usual. The occurrence of blood or mucus in the stool suggests the presence of an ulcerative process in the bowel. Alternating periods of constipation and diarrhea may be complained of. Intestinal colic may however be the first evidence of the disease.

Diagnosis—The occurrence of intestinal colic and distention affords satisfactory evidence of the presence of an organic block in the bowel. The location of the distended intestinal coils is easily obtained on roentgen examination.

Differential Diagnosis—The exact nature of the obstructing agent may not be determinable until at operation. Incarceration of a gallstone in the intestinal tract, enteric intussusception and obstruction by an adhesive band cannot be adequately differentiated.

In obstruction of the colon a functional spastic ileus concerning essentially the large bowel may give rise to confusion. The picture of an organic occlusion in the bowel may be simulated closely and many patients with spastic obstruction of the colon have been operated on under the diagnosis of mechanical obstruction due to neoplastic stricture in the sigmoid flexure. Inspection of the roentgenogram showing the extension of the gaseous distention to the rectum and the administration of a barium enema usually serve to differentiate these conditions if the possibility of this confusing occurrence is only borne in mind. Occasionally compression of the pelvic colon from a pelvic mass may be mistaken for an intrinsic obstruction in the intestine but physical examination and the history usually serve to differentiate this condition. Diverticulitis and obstruction by neoplasm often cannot be distinguished without the aid of the microscope.

Prognosis—The mortality of intestinal obstruction due to malignancy is in the neighborhood of 50 per cent. Thus unwarranted mortality is compounded in part through continuance of surgeons to perform cecostomy in operation which cannot be done aseptically in the presence of great distention. General adoption of the type of op-

erative procedure depicted in figure 565 will lead to a lowering of the mortality. Benign strictures carry considerably less risk.

Treatment—Frequently patients with subacute obstruction of the small intestine due to stricture can be tided over to a non-obstructive phase by the employment of suction applied to an intying duodenal tube and the condition rectified in one operative procedure. If, however, the distention is

low, is often the wisest procedure. Occasionally an enterocanastomosis followed by excision of the lesion at a subsequent operation may be performed.

In obstruction of the colon a decompression type of operation is in order. Because of the action of the ileocecal valve, suction applied to a duodenal tube is of no value, except in cases in which the obstructive element is mild. Here, frequently the patient

Fig. 565.—Technique of decompressing the distended colon. Upper left sketch of a roentgenogram. A five cent piece (a) was taped over the umbilicus (b). Upper right the method of deflating the colon on completion of the operation is shown. After a few such aspirations, the bowel is incised, and before it is finally cut across a tube is inserted. The tension in the bowel is determined before its contents are aspirated. This aseptic type of operation for acute obstruction is attended by a low mortality.*

great and the nature of the obstruction remains somewhat in doubt, operation is in order. No extensive surgical procedure should be contemplated in the presence of obstruction, particularly operative procedures which require opening of the bowel. Enterostomy frequently suffices. Resection and anastomosis carry a high mortality and should not be attempted under ordinary circumstances. Exteriorization of the loop of intestine, especially if the obstruction is

may be carried over to a non-obstructive phase by such means and the lesion itself directly attacked. In acute obstruction it might appear that appendicostomy or cecostomy would be the operative procedure of choice. The former deviates the fecal stream incompletely; an aseptic cecostomy is difficult to perform in the presence of an acutely distended colon. The writer has come to em-

ploy a transverse incision directly over the transverse colon (Fig 565) in dealing with acute obstruction of the colon. It can be done aseptically and with little risk and constitutes a satisfactory and effectual method of decompressing the distended colon. When the obstruction is in the hepatic flexure or the ascending colon, that distended segment of gut may be exteriorized and tapped as indicated in figure 565. An alternative method would be to perform ileostomy on the terminal portion of the ileum pushing the catheter through the ileocecal valve into the distended cecum.

2 OBSTRUCTION

a Intestinal Obstruction Due to Gallstones.—*Etiology*—In cases of obstructions due to gallstones there is invariably an abnormal communication between the biliary passages and the intestine. Most frequently this internal biliary fistula is established between the gallbladder and the duodenum though communication with some other portion of the alimentary canal such as the stomach jejunum ileum or colon is occasionally found. Infrequently the communication is between the common bile duct and a portion of the intestinal canal. Instances are reported in which an intestinal obstruction is said to have occurred in the absence of such an abnormal communication. In such instances however it would appear unlikely that the gallstones were large enough to cause a mechanical block of the bowel for rarely do gallstones of that size pass through the ampullary opening of the choledochus. However occasionally gallstones not large enough to block the lumen of the bowel do cause symptoms of bowel obstruction. In such instances however a dynamic or spastic obstruction must be brought about through the agency of the stone. Obstruction due to a gallstone though infrequent is decidedly not a rare occurrence. The usual site of lodgment of the stone is the lower portion of the ileum but occasionally it is found in the jejunum or even in the sigmoid flexure of the colon. Stones large enough to occlude the lumen of the intestine are usually about the size of a walnut. Round stones are much more likely to cause obstruction than stones of equal weight but greater length. Enlargement of a gallstone during its passage through the intestine may also occur. It is especially likely to happen if the stone remains in any portion of the intestine for a considerable length of time and particularly when medicaments such as bisulphate of calcium or magnesium carbonate are taken orally. Instances in which obstruction due to gallstones has occurred in the same person more than once are on record. Gallstones obstruct the bowel three times more frequently in women than in men. Persons of middle life and a advanced years are most often attacked.

Pathology—Obstruction due to a gallstone is usually of the simple variety in which a mechanical block alone is present. Occasionally such an obstruction partakes of the nature of a volvulus because of the fact

that when fluid and gas accumulate above the point of obstruction owing to the increased weight of the segment such a loop may undergo torsion. A tendency for perforating ulcer to form at the site of incarceration of the stone in the bowel is well known.

Symptoms—There are no clinical features peculiar to this type of obstruction. Frequently an antecedent history of disease of the gallbladder or cholangitis may be obtained. Intestinal colic in the presence of unexplained jaundice should suggest the possibility of obstruction due to a gallstone.

Diagnosis—Though the presence of intestinal obstruction is rarely demanding of proof, an accurate preoperative diagnosis is rarely made. Occasionally the stone may be visualized in the distended bowel on the roentgenogram.

Prognosis—The outlook is somewhat grave (mortality of about 50 per cent). This is accounted for partly by the fact that the patients frequently come late to operation and partly because the opening of the intestine in order to extract the stone in the presence of obstruction may result in peritonitis. Opening of the bowel and removal of the stone without soiling will lead to a lessening of the mortality. Of the last 4 patients operated on at the University Hospitals, none died.

Treatment—Operation at the earliest possible moment is the safest procedure. The stone must be removed without spillage. Aseptic removal can be effected by placement of presection sutures which are pulled aside for the placement of the transverse incision in the bowel. As soon as the stone is removed the sutures are tightened and tied.

b Intestinal Obstruction Due to Foreign Bodies—Children occasionally swallow pebbles, coins or circular whistles that may give rise to intestinal obstruction but the majority of these foreign bodies pass through the intestinal canal without special event. Demented or hysterical persons not infrequently swallow objects of the most unusual character that lodge in the intestine and cause obstruction. Pins, needles, forks, teeth, spoons, nails and screws have been removed. Indigestible materials such as bran licks of oats and fruit stones have been known to accumulate in the intestine or to contribute to the formation of masses in the bowel which cause obstruction. Should a structure exist in the intestine such bodies are particularly likely to obstruct it.

c Obstruction Due to Enteroliths—Enteroliths occasionally give rise to obstruction in man but commonly in horses. Their occurrence in the human vermiform
